Contents

Contributors *xiii*
Preface *xix*
About the Companion Website *xxi*

Section 1 Principles of Pharmacology *1*

1 **Veterinary Pharmacology: An Introduction to the Discipline** *3*
Jim E. Riviere and Mark G. Papich

2 **Absorption, Distribution, Metabolism, and Elimination** *8*
Jim E. Riviere

3 **Pharmacokinetics** *41*
Jim E. Riviere

4 **Mechanism of Drug Action and Pharmacokinetics/ Pharmacodynamics Integration in Dosage Regimen Optimization for Veterinary Medicine** *65*
Pierre-Louis Toutain

5 **Principles of Pharmaceutics and Veterinary Dosage Forms** *87*
Raafat M. Fahmy and Marilyn N. Martinez

Section 2 Drugs Acting on the Autonomic Nervous System *111*

6 **Introduction to the Autonomic Nervous System and Autonomic Pharmacology** *113*
Joshua A. Rowe, Rose M. McMurphy, Barbara J. Lutjemeier, and Michael J. Kenney

7 **Adrenergic Receptor Agonists and Antagonists** *131*
Rose M. McMurphy, Elizabeth G. Davis, Amy J. Rankin, Daniel A. Frese, Barbara J. Lutjemeier, and Michael J. Kenney

8 **Cholinergic Pharmacology: Autonomic Drugs** *151*
Rose M. McMurphy, Elizabeth G. Davis, Amy J. Rankin, Marjory A. Artzer, Barbara J. Lutjemeier, and Michael J. Kenney

Section 3 Anesthetics and Analgesics, and Drugs Acting on the Central Nervous System *165*

9 **Introduction to Drugs Acting on the Central Nervous System and Principles of Anesthesiology** *167*
Peter J. Pascoe and Eugene P. Steffey

10 **Neuromuscular Blocking Agents** *194*
Diane E. Mason and Christopher L. Norkus

11 Inhalation Anesthetics *216*
Robert J. Brosnan and Eugene P. Steffey

12 Injectable Anesthetic Agents *247*
Lysa P. Posner

13 Opioid Analgesic Drugs *281*
Butch KuKanich and Mark G. Papich

14 Sedatives and Tranquilizers *324*
Lysa P. Posner

15 Local Anesthetics *369*
Thomas W. Vickroy

16 Euthanizing Agents *387*
Anna Hampton

17 Anticonvulsant Drugs *395*
Mark G. Papich

18 Drugs Affecting Animal Behavior *416*
Margaret E. Gruen, Barbara L. Sherman, and Mark G. Papich

Section 4 Autacoids and Antiinflammatory Drugs *449*

19 Histamine, Serotonin, and their Antagonists *451*
Wolfgang Bäumer

20 Analgesic, Antiinflammatory, Antipyretic Drugs *467*
Peter Lees

Section 5 Drugs Acting on the Cardiovascular System *501*

21 Digitalis, Positive Inotropes, and Vasodilators *503*
Clarke E. Atkins and Marisa K. Ames

22 Antiarrhythmic Agents *537*
Kathryn M. Meurs and Jim E. Riviere

Section 6 Drugs Affecting Renal Function and Fluid–Electrolyte Balance *553*

23 Principles of Acid–Base Balance: Fluid and Electrolyte Therapy, Blood Substitutes *555*
Maya M. Scott-Garrard, Melisa Rosenthal, and Deborah T. Kochevar

24 Diuretics and Renal Pharmacology *593*
Butch Kukanich and Deborah T. Kochevar

Section 7 Drugs Acting on Blood and Blood Elements *623*

25 Anticoagulant, Antiplatelet, and Hemostatic Drugs *625*
Mark G. Papich

Section 8 Endocrine Pharmacology *647*

26 Hypothalamic and Pituitary Hormones *649*
Srujana Rayalam, Margarethe Hoenig, and Duncan C. Ferguson

27 Hormones Affecting Reproduction *674*
Wolfgang Bäumer, C. Scott Bailey, and John Gadsby

28 Thyroid Hormone and Antithyroid Drugs *691*
Duncan C. Ferguson

29 Glucocorticoids, Mineralocorticoids, and Adrenolytic Drugs *729*
Duncan C. Ferguson and Margarethe Hoenig

30 Drugs Influencing Glucose Metabolism *763*
Margarethe Hoenig

Section 9 Chemotherapy of Microbial Diseases *779*

31 Antiseptics and Disinfectants *781*
Megan E. Jacob

32 Sulfonamides and Potentiated Sulfonamides *796*
Mark G. Papich

33 β-Lactam Antibiotics: Penicillins, Cephalosporins, and Related Drugs *826*
Mark G. Papich

34 Tetracycline Antibiotics *858*
Mark G. Papich and Jim E. Riviere

35 Aminoglycoside Antibiotics *877*
Mark G. Papich and Jim E. Riviere

36 Chloramphenicol and Derivatives, Macrolides, Lincosamides, and Miscellaneous Antimicrobials *903*
Mark G. Papich

37 Fluoroquinolone Antimicrobial Drugs *953*
Mark G. Papich

38 Antifungal and Antiviral Drugs *988*
Jennifer L. Davis and Lara Maxwell

Section 10 Chemotherapy of Parasitic Diseases *1033*

39 Antinematodal Drugs *1035*
Carlos E. Lanusse, Juan M. Sallovitz, Sergio F. Sanchez Bruni, and Luis I. Alvarez

40 Anticestodal and Antitrematodal Drugs *1081*
Carlos E. Lanusse, Luis I. Alvarez, and Guillermo L. Virkel

41 Macrocyclic Lactones: Endectocide Compounds *1102*
Carlos E. Lanusse, Fernanda A. Imperiale, and Adrian L. Lifschitz

42 Antiprotozoan Drugs *1128*
Jennifer L. Davis and Jody L. Gookin

43 Ectoparasiticides *1166*
Ronald E. Baynes

Section 11 Specialty Areas of Pharmacology *1189*

44 Chemotherapy of Neoplastic Diseases *1191*
Luke A. Wittenburg and Daniel L. Gustafson

45 Immunosuppressive Drugs *1226*
Mark G. Papich

46 Drugs for Treating Gastrointestinal Diseases *1245*
Mark G. Papich

47 Dermatopharmacology: Drugs Acting Locally on the Skin *1278*
Jim E. Riviere and Rosanna Marsella

48 Drugs that Affect the Respiratory System *1302*
Mark G. Papich

49 Ophthalmic Pharmacology *1321*
Alison Clode

50 Pharmacogenomics *1332*
Katrina L. Mealey

51 Considerations for Treating Minor Food-Producing Animals with Veterinary Pharmaceuticals *1345*
Lisa A. Tell, Margaret Oeller, Tara Marmulak, and Ronette Gehring

52 Unique Considerations Pertaining to the Use of Drugs in Food Animals *1358*
Michael D. Apley

53 Pharmacology in Aquatic Animals *1373*
Ron A. Miller

54 Zoological Pharmacology *1395*
Robert P. Hunter

Section 12 Regulatory and Other Considerations *1405*

55 The Regulation of Animal Drugs *1407*
Steven D. Vaughn and Marilyn N. Martinez

56 Veterinary Pharmacy *1427*
Gigi Davidson and Mark G. Papich

57 Medication Control Programs in Performance Animals *1439*
Cynthia A. Cole

58 Pharmacovigilance *1448*
John D. Baker, Susan J. Bright-Ponte, and Lee Anne M. Palmer

59 **Dosage Forms And Veterinary Feed Directives** *1459*
Geof Smith and Jim E. Riviere

60 **Evidence-Based Pharmacotherapy** *1465*
Ronette Gehring

61 **Chemical Residues In Tissues Of Food Animals** *1469*
Jim E. Riviere

Index *1481*

Preface

This current volume marks the tenth edition of *Veterinary Pharmacology and Therapeutics*, first published some six decades ago by Dr. L. Meyer Jones. Both the discipline and book have dramatically changed since the first edition came out in 1954. Entirely new therapeutic classes of drugs are now used and veterinary pharmacotherapy is much more quantitative, mechanism-based, and firmly integrated into clinical medicine than in past years. Early editions were intended to be simply a standard textbook for students taking a pharmacology course in the veterinary curriculum. However, the educational culture and environment of veterinary colleges have evolved, making the audience of the current edition much broader than the veterinary medical student alone. Interns and residents in various medical disciplines, including clinical pharmacology, graduate students in comparative biomedical sciences, laboratory animal specialists, animal health drug developers and regulators, and as always researchers across diverse fields, all view this text as the standard reference source and supplemental reading for comparative pharmacology at all levels of professional and graduate school curriculums. This role as the primary veterinary pharmacology reference textbook has become even more important as so-called open textbook initiatives become mandatory in more veterinary colleges.

Because of the unique role this text serves in comparative and veterinary pharmacology across the globe, we have endeavored to significantly update and revise this current edition with substantial rewriting and editing of the majority of chapters. We have enlisted the collaboration of authors who are experts in their respective fields and instructed them to focus on drugs that are currently used in veterinary practice. To accommodate these additions, we have removed discussion of older drugs no longer routinely employed and instead direct the reader interested in these compounds to consult earlier editions of the text. As in the last edition, we have also presented therapeutic agents both by pharmacological class but also regrouped into therapeutic applications to insure clinical relevance. We remain cognizant of the public health responsibilities of veterinarians in production animal practice and have endeavored to discuss issues related to updated regulations, as well as avoidance of both antimicrobial drug resistance and violative tissue residues in edible products from food-producing animals.

We are indebted to the authors of the text who tried as best as possible to adhere to deadlines despite their busy schedules, to the excellent support of the publisher's staff at Wiley-Blackwell, as well as the numerous staff and students at both Kansas State and North Carolina State Universities who aided in arriving at this final product. We hope the reader finds that this tenth edition of *Veterinary Pharmacology and Therapeutics* serves them well and provides a solid foundation for the rational use of drugs in veterinary medicine.

Jim E. Riviere and Mark G. Papich

Veterinary Pharmacology: An Introduction to the Discipline

Jim E. Riviere and Mark G. Papich

Pharmacology is the science that broadly deals with the physical and chemical properties, actions, absorption, and fate of chemical substances termed *drugs* that modify biological function. It is a discipline that touches most areas of human and veterinary medicine and closely interfaces with pharmaceutical science and toxicology.

History of Pharmacology

As long as humans and their animals have suffered from disease, chemical substances have played a role in their treatment. Substances obtained from plants and animals or their products were used according to precise prescriptions through antiquity. The mechanism attributed to why these substances were effective are deeply rooted in the beliefs and mythologies of each culture, as were the rituals involved in their preparation.

The early history of pharmacology parallels human efforts to compile records of ailments and their remedies. The earliest recorded compilation of drugs, the *Pen Tsao*, consisted of a list of herbal remedies compiled in the reign of Chinese Emperor Shennung in 2700 B.C. Classic examples of medicinal use of chemicals, herbs, and other natural substances are found in the recorded papyri of ancient Egypt. The *Kahun Papyrus,* written about 2000 B.C., lists prescriptions for treating uterine disease in women and specifically addresses veterinary medical concerns. The *Ebers Papyrus,* written in 1150 B.C. is a collection of folklore covering 15 centuries of history. It is composed of over 800 prescriptions for salves, plasters, pills, suppositories, and other dosage forms used to treat specific ailments.

The ancient Greek philosopher–physicians of 500 B.C. taught that health was maintained by a balance of "humors," which were affected by temperature, humidity, acidity, and sweetness, rather than to the direct actions of gods or demons. Disease was treated by returning these humors to a proper balance. Hippocrates (460–370 B.C.) was an ancient Greek physician of the Age of Pericles. He is referred to as the "father of medicine" in recognition of his lasting contributions to the field as the founder of the Hippocratic school of medicine. He was a firm believer in the healing powers of nature, conducted systematic observations of his patients' symptoms, and began moving the practice of medicine from an art to a systematic clinical science. The first true *material medica*, a compilation of therapeutic substances and their uses, was compiled in 77 A.D. by Aristotle's student Dioscorides, while serving as a surgeon in Nero's Roman Legion traveling throughout the Mediterranean. This served as the basis for the later works of Galen (131–201) that emerged as the authoritative material medica for the next 1,400 years! In fact, some pharmaceutical preparations consisting of primarily herbal or vegetable matter are still referred to as galenical preparations. As the Dark Ages descended upon Europe, such scholarship transferred to Byzantium, where in fact a veterinary compilation for farm animal treatments, *Publius Vegetius,* was compiled in the fifth century.

It took until the Renaissance to awaken the spirit of discovery in Europe. The Swiss physician Theophrastus Bombastus von Hohenheim (1492–1541), known as Paracelsus, introduced the clinical use of laudanum (opium) and a number of tinctures (extracts) of various plants, some of which are still in use today. He is remembered for using drugs for specific and directed purposes, and for the famous dictum "All substances are poisons; there is none which is not a poison. The proper dose separates a poison from a remedy." As these practices took root, official compilations of medicinal substances, their preparation, use, and dosages, started to appear in Europe. These publications, termed *pharmacopeia*, provided a unifying framework upon which the pharmaceutical sciences emerged. The first printed pharmacopeia, titled the *Dispensatorium,* was published by Valerius Cordus in 1547 in Nuremberg, Germany. Local publications emerged in different European cities, with two pharmacopeias published in London in 1618. The *Edinburgh Pharmacopoeia* published in 1689 became the most influential during this period. It took until the mid-19th century before truly national pharmacopeias took

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

hold, with the first *United States Pharmacopeia* published in 1820. The first *United States Pharmacopeia* has been given the title USP-0; the current edition of the *United States Pharmacopeia* is titled USP-39 and the National Formulary titled NF 34, which includes excipients. There was also a British pharmacopeia first published in 1864 and the *British Pharmacopeia* continues to be published today.

The history of pharmacology parallels the development of modern medicine and the realization that specific natural products and substances may cure specific diseases. The 16th and 17th centuries were marked by great explorations and the beginning of medical experimentation. In 1656, Sir Christopher Wren made the first intravenous injection of opium in a dog. The bark of the cinchona tree was brought by Jesuits from South America for use of treatment of malaria. In 1783, the English physician William Withering reported on his experience in the use of extracts from the foxglove plant to treat patients with "dropsy," a form of edema most likely caused by congestive heart failure.

In the early 1800s the French physiologist–pharmacologist Megendie, working with the pharmacist Pelletier, studied the effects of intravenous injections of ipecac, morphine, strychnine, and other substances on animals. Megendie was the first to prove that chemicals can be absorbed into the vascular system to exert a systemic effect. A prolific scientist, he also published a formulary that survived through eight editions from 1821 to 1836. The Spanish physician Orfila published the results of many experiments in a book entitled *Toxicologie Generale* in 1813. A student of Megendie, the famous physiologist Claude Bernard, and others, showed in the mid-1800s that the active ingredient of foxglove botanical preparations was digitalis, and its action was on the heart. We continue to use digoxin today for the treatment of congestive heart failure in humans and animals. The important aspect of these early studies was that they used the experimental paradigm for demonstrating chemical activity, establishing both the philosophy and methods upon which the discipline of modern pharmacology is based.

The term *Pharmakologie* was applied to the study of material medica by Dale in London as early as 1692; however, it is generally regarded that the biochemist Rudolph Buchheim in the Baltic city of Dorpat established the first true experimental laboratory dedicated to pharmacology in the mid-18th century. He published some 118 contributions on a variety of drugs and their actions, and argued for pharmacology to be a separate discipline distinct from material medica, pharmacy, and chemistry. His work included in 1849 a textbook *Beiträge zur Ärzneimittellehre,* which classified drugs based on their pharmacological action in living tissue. He deleted traditional remedies if he could not demonstrate their action in his laboratory. This is the beginning of what we now know as *evidence-based pharmacology,* which requires that a chemical be termed a drug only if a specific action in living tissues can be demonstrated.

His student, Oswald Schmiedeberg, became a Professor of Pharmacology at the University of Strasbourg in 1872 and took upon himself the goal of making pharmacology an independent scientific discipline based upon precise experimental methodology that ultimately displaced material medica in medical school curriculums throughout Europe by the end of the 19th century and by the early 20th century in America. He studied the correlation between the chemical structure of substances and their effectiveness as narcotics. He published some 200 publications as well as an authoritative textbook in 1883 that went through seven editions. This text classified drugs by their actions and separated experimental pharmacology from therapeutics. In addition he founded and edited the first pharmacology journal *Archiv für experimentelle Pathologie und Pharmakologie* in 1875, which in 2007 published volume 375 as *Naunym-Schmiedeberg's Archives of Pharmacology.* His more than 150 students spread the discipline of pharmacology throughout Europe and America.

One of his students, Dr. John Abel, held the first full-time professorship in pharmacology at the University of Michigan and is considered by some to be the father of American pharmacology. Professor Abel then moved to Johns Hopkins Medical School where he continued his basic pharmacological research and founded the *Journal of Biological Chemistry* as well as the *Journal of Pharmacology and Experimental Therapeutics.* He was instrumental in founding the *American Society of Pharmacology and Experimental Therapeutics* in 1908.

From these origins, the various disciplines of pharmacology grew, the common factor being the focus in experimental methods to discover and confirm drug actions. Today, the basic philosophy remains unchanged, although modern techniques are grounded in analytical chemistry, mathematical models, and the emerging science of pharmacogenomics. Such so-called "big data" approaches coupled with high throughput screening approaches are the primary tools now used in drug discovery.

Veterinary Pharmacology

The development of veterinary pharmacology generally paralleled that of human pharmacology. However, there is archeological evidence of an Indian military hospital for horses and elephants from 5000 B.C., at which time there also existed an extensive medical education program at the Hindu university at Takkasila. The formal discipline of veterinary pharmacology has its origins in the establishment of veterinary colleges and hospitals in France, Austria, Germany, and the Netherlands in the 1760s as a response to epidemics of diseases such as rinderpest that decimated animal populations throughout Western Europe. The Royal College of Veterinary Surgeons was established in London in 1791 followed in 1823 by the Royal (Dick) School of Veterinary Studies in Edinburgh. The earliest veterinary colleges were established in the United States in 1852 in Philadelphia and in Boston in 1854; however, both were short-lived. Modern existing North American veterinary schools founded in the late 1800s, and which continue in operation, include those in Iowa, Ohio, Ontario, Pennsylvania, and New York.

In these early colleges, teaching of pharmacology in veterinary schools was essentially *materia medica*, and remained closely aligned with parallel efforts occurring in medical schools, especially when colleges were located on the same campuses. This was evident in the European schools, with a separation really occurring in the 20th century. However, this linkage was not absolute. An early mid-19th century veterinary textbook *The Veterinarian's Vade Mecum* was published by John Gamgee in England. It was essentially a *materia medica* and did not reflect the biological-based classification system for substances used by Professor Buchheim in the same period. The first American professor of therapeutics at the School of Veterinary Medicine at Iowa State was a physician, D. Fairchild. Similarly, a textbook of veterinary pharmacology *Veterinary Material Medica and Therapeutics* published by the School of Veterinary Medicine at Harvard was authored by Kenelm Winslow, a veterinarian and physician. This book, the eighth edition of which was published in 1919, began to follow the modern thrust described earlier of relating drug actions to biological effects on tissues. It seems veterinary medicine's 21st-century preoccupation with the "one-medicine" concept has deep historical roots.

The history of veterinary pharmacology has been reviewed by Lees, Fink-Gremmels, and Toutain (2013). They reviewed the past history and current status of the science, particularly the developments in the last 35 years. The authors analyzed publication data and showed the tremendous increase in scientific articles focusing on veterinary pharmacology since 1975. The important event, which fully shifted veterinary pharmacology from one focused on *materia medica* to the actual science of pharmacology, was the publication by Professor L. Meyer Jones in 1954 of the first edition of the textbook you are now reading. From this point forward, veterinary pharmacology positions have existed in Colleges of Veterinary Medicine throughout the world, the structure of which are often a reflection of local university history, priorities, and academic structure.

Organized veterinary pharmacology occurred rather simultaneously in Europe and the Americas. The American Academy of Veterinary Pharmacology and Therapeutics (AAVPT) was founded in 1977 and the European Association for Veterinary Pharmacology and Toxicology (EAVPT) in 1978. These two organizations, together with the British Association for Veterinary Clinical Pharmacology and Therapeutics, launched the *Journal of Veterinary Pharmacology and Therapeutics* (JVPT) in 1978. Its founder, Dr. Andrew Yoxall, hoped that the journal would improve coordination and communication among pharmacologists and veterinary clinicians, and designed it for the publication of topics relating both to the clinical aspects of veterinary pharmacology, and to the fundamental pharmacological topics of veterinary relevance. Now in its 40th year of publication, edited by Dr. Riviere and also cosponsored by both the American College of Veterinary Clinical Pharmacology (ACVCP) and the Chapter of Veterinary Pharmacology of the Australian College of Veterinary Scientists, this journal remains the primary outlet for publication of veterinary-related science-based pharmacology investigations.

The discipline of clinical pharmacology is more directly related to applying pharmacological principles – particularly pharmacokinetics – to clinical patients. Fellows of the AAVPT formed the AVMA-recognized board certified specialty – the American College of Veterinary Clinical Pharmacology (ACVCP) – in 1991. The establishment of the ACVCP paralleled the establishment of the American Board of Clinical Pharmacology (ABCP) – the human medical counterpart – in the same year with the cooperation of the American College of Clinical Pharmacology. In order to promote a focus on applying higher-level mathematical techniques to veterinary pharmacology, the international Animal Health Modeling and Simulation Society (AHM&S) was founded in 2012.

Regulations and Standards

A different perspective on the development of veterinary pharmacology over the last century is the development of regulatory bodies to insure that safe, effective, and pure drugs reach commerce. As discussed above, *material medica* and *pharmacopeia* were in large part the force that held pharmacology together as a discipline for centuries. Since 1820, the *United States Pharmacopeia (USP)*, a private, not-for-profit organization, has endeavored to establish standards for strength, quality, purity, packaging, and labeling for all manufacturers of pharmaceutical substances in the United States. It took until 1990, under the pressure of Dr. Lloyd Davis, one of the founding fathers of AAVPT and ACVCP, to have USP specifically develop Committees to develop USP standards and information for veterinary drugs. Until this time, veterinary drugs whose manufacturers desired the "USP Label" processed drugs through committees that were largely populated by experts in human pharmaceutical sciences and medicine. Additional contributions of veterinary pharmacists to our discipline are described in Chapter 56 of this book.

In the 20th century, due to the proliferation of charlatans and fraud in manufacture and distribution of so-called "pure" medicinal products, coupled with serious human health calamities due to nonregulated drugs reaching the market, Congress in 1927 established the Food, Drug and Insecticide Administration, which later became known as the Food and Drug Administration (FDA). In 1938, the pivotal Federal Food, Drug and Cosmetic Act was passed, giving the FDA the authority to regulate animal drugs by requiring evidence of product safety before distribution. In 1959, a veterinary medical branch was developed as a division and the Food Additive Amendments Act was passed, which gave FDA authority over animal food additives and drug residues in animal-derived foods. A Bureau of Veterinary Medicine, with Dr. M. Clarkson as its first director, was established in 1965 to handle the increasing regulatory responsibilities of animal drugs. Today, the FDA Center for Veterinary Medicine, directed by Dr. Steven Solomon, is the primary regulatory body for veterinary drugs in the United States. The interested reader should consult Chapter 55 of the present text for a more in-depth discussion of the current state of veterinary regulatory authority.

In addition to the standard-setting activities of the USP, veterinary pharmacologists have contributed to other standard-setting organizations. Veterinary pharmacology has had its influence on national and international standard-setting organizations and is contributing to the "one health" concept of medicine. Veterinary pharmacologists and microbiologists have worked together to form the Veterinary Susceptibility Testing Subcommittee (VAST) of the Clinical and Laboratory Standards Institute (CLSI, formerly called NCCLS, www.CLSI.org). This subcommittee first met in 1993 and has now published four editions and three supplements of the public standards for identifying, and testing antimicrobial susceptibility for bacteria isolated from animals. The CLSI-VAST is still the only standard for testing antimicrobial susceptibility for animal pathogens in the world and contributes to the global effort to monitor antimicrobial resistance among bacteria.

What is Veterinary Pharmacology?

As can be appreciated from the breadth of material covered by the present textbook, veterinary pharmacology covers all aspects of using chemical and biological substances to treat diseases of animals. The basic principles of drug action are identical across veterinary and human pharmacology. Thus the principles of absorption, distribution, metabolism, and elimination covered here are the same as in any human pharmacology text, except for a focus on crucial species differences in anatomy, physiology, or metabolism that would alter these processes. The topics of pharmacodynamics, pharmacogenomics, and pharmacokinetics are also species-independent in basic concepts. These topics encompass what truly should be termed *comparative pharmacology*.

The subspecialties of veterinary pharmacology cover all those seen in human pharmacology, the classification of which can be seen from the division of the present text. These include classifying drugs as acting on the nervous, inflammatory, cardiovascular, renal, endocrine, reproductive, ocular, gastrointestinal, respiratory, and dermal systems as well as those used in chemotherapy of microbial, parasitic, and neoplastic diseases. Because of the potential exposure and heavy parasite load of both companion and production animals, antiparasitic drugs will get deeper coverage than seen in a human pharmacology text. There are a number of specialty areas that also reflect unique aspects of veterinary medicine, including aquatic, zoo, and avian species, as well as aspects of regulations related to racing animals and using drugs in food-producing animals with the resulting production of chemical residues and potential human food safety issues. This is simply not an issue in human medicine.

The discipline is often simply divided into basic and clinical pharmacology, the distinction being whether studies are conducted in healthy or diseased animals, studying experimental models or natural disease states, or involve laboratory or clinical studies in an actual veterinary clinical situation. However, the common denominator that separates a veterinary pharmacologists from our human pharmacology colleagues is dealing with species differences in both disposition and action of drugs.

Comparative pharmacology is the true common theme that courses through the blood of all veterinary pharmacologists, be they basic or clinical in orientation. How does a drug behave in the species being treated? Is the disease pathophysiology similar across species? Do dosages need to be adjusted? Are microbial susceptibilities for pathogens different? Is a drug absorbed, eliminated, or metabolized differently in a particular species or breed? Can the dosage form developed for a dog be used in an equine patient? Are there unique individual variations in the population due to pharmacogenomic variability that would alter a drug's effect in this patient? Are there unique species-specific toxicological effects for the drug in this patient? Is there a potential for drug–drug, drug–diet, or drug–environment interactions? Will this animal or its products be consumed by humans as food, and thus are potential residues from drug therapy a concern? All of these questions are addressed in the chapters that follow in this textbook.

The focus of veterinary pharmacology is to provide a rational basis for the use of drugs in a clinical setting in different animal species. These principles are fully discussed in the remainder of this text. The practicing veterinarian should appreciate every day that when a drug is given to a patient in his/her care, an experiment in clinical pharmacology is being conducted. The astute and successful practitioner will use principles of pharmacology to assure that the correct drug and dosage regimen is selected for the diagnosis in hand, that proper clinical outcomes will be assessed for both assuring efficacy and avoiding adverse effects, and finally that if a food-producing animal is being treated, proper caution is taken to insure the safety of animal-derived products to the human consumer.

Absorption, Distribution, Metabolism, and Elimination

Jim E. Riviere

The four key physiological processes that govern the time course of drug fate in the body are absorption, distribution, metabolism, and elimination, the so-called *ADME processes*. Pharmacokinetics, the study of the time course of drug concentrations in the body, provides a means of quantitating ADME parameters. When applied to a clinical situation, pharmacokinetics provides the practitioner with a useful tool to design optimally beneficial drug dosage schedules for each individual patient. In the research and premarketing phase of drug development, it is an essential component in establishing effective yet safe dosage forms and regimens. An understanding of pharmacokinetic principles allows more rational therapeutic decisions to be made. In food animals, pharmacokinetics provides the conceptual underpinnings for understanding and utilizing the withdrawal time to prevent violative drug residues from persisting in the edible tissues of food-producing animals. A working knowledge of this discipline provides the framework upon which many aspects of pharmacology can be integrated into a rational plan for drug usage.

An Overview of Drug Disposition

To fully appreciate the ADME processes governing the fate of drugs in animals, the various steps involved must be defined and ultimately quantitated. The processes relevant to a discussion of the absorption and disposition of a drug administered by the intravenous (IV), intramuscular (IM), subcutaneous (SC), oral (PO), or topical (TOP) routes are illustrated in Figure 2.1. The normal reference point for pharmacokinetic discussion and analysis is the concentration of free, non-protein-bound drug dissolved in the serum (or plasma), because this is the body fluid that carries the drug throughout the body and from which samples for drug analysis can be readily and repeatedly collected. For the majority of drugs studied, concentrations in the systemic circulation are in equilibrium with the extracellular fluid of well-perfused tissues; thus, serum or plasma drug concentrations generally reflect extracellular fluid drug concentrations.

A fundamental axiom of using pharmacokinetics to predict drug effect is that the *drug must be present at its site of action in a tissue at a sufficient concentration for a specific period of time to produce a pharmacological effect.* Since tissue concentrations of drugs are reflected by extracellular fluid and thus serum drug concentrations, a pharmacokinetic analysis of the disposition of drug in the scheme outlined in Figure 2.1 is useful to assess the activity of a drug in the in vivo setting.

This conceptualization is especially important in veterinary medicine where species differences in any of the ADME processes may significantly affect the extent and/or time course of drug absorption and disposition in the body. By dividing the overall process of drug fate into specific phases, this relatively complex situation can be more easily handled. It is the purpose of this chapter to overview the physiological basis of absorption, distribution, metabolism, (biotransformation) and elimination. This will provide a basis for the chapter on pharmacokinetics that will deal with quantitating these processes in more detail.

Despite the myriad of anatomical and physiological differences among animals, the biology of drug absorption and distribution, and in some cases even elimination, is very similar in that it involves drug molecules crossing a series of biological membranes. As illustrated in Figure 2.2, these membranes may be associated with either several layers of cells (tissue) or a single cell, and both living and dead protoplasm may be involved. Despite the different biochemical and morphological attributes of each of these membranes, a unifying concept of biology is the basic similarity of all membranes, whether they be tissue, cell, or organelle. Although the specific biochemical components may vary, the fundamental organization is the same. This fact simplifies the understanding of the major determinants of drug absorption, distribution, and excretion.

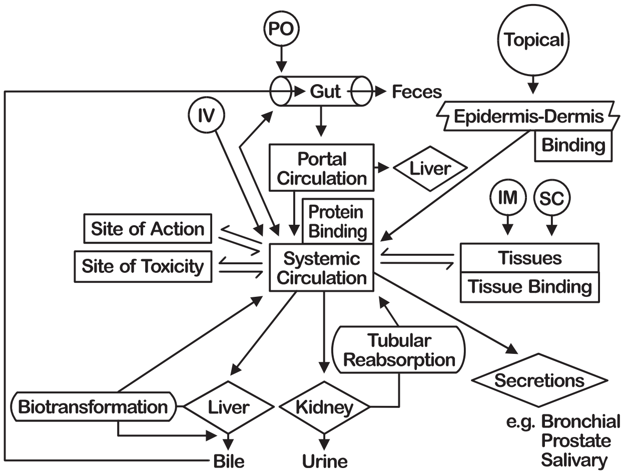

Figure 2.1 Basic schema by which drug is absorbed, distributed, metabolized, and excreted from the body. These processes are those that form the basis for developing pharmacokinetic models.

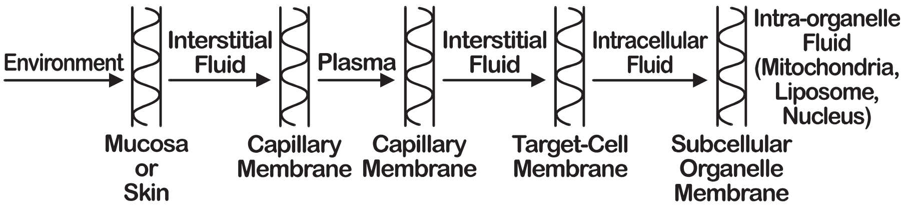
These membrane barriers often directly or indirectly define the nature of compartments or other mathematical modules in pharmacokinetic models. Biological spaces are defined by the restrictions on drug movement imposed by these barriers. The most effective barriers are those that protect the organism from the external environment. These include the skin as well as various segments of the gastrointestinal and respiratory tract, which also protect the internal physiological milieu from the damaging external environment. However, the gastrointestinal and respiratory barriers are modified deep within the body to allow for nutrient and gas exchange vital for life. The interstitial fluid is a common compartment through which any drug must transit, either after absorption on route to the blood stream or after delivery by blood to a tissue on route to a cellular target. Capillary membranes interfacing with this interstitial fluid compartment are relatively porous due to the fenestrae that allow large molecules to exchange between tissues and blood. Membranes define homogeneous tissue compartments and membranes must be traversed in all processes of drug absorption and disposition.

All cellular membranes appear to be primarily lipid bilayers into which are embedded proteins that may reside on either surface (intra- or extracellular) or traverse the entire structure. The lipid leaflets are arranged with hydrophilic (polar) head groups on the surface and hydrophobic (nonpolar) tails forming the interior. The specific lipid composition varies widely across different tissues and levels of biological organization. The location of the proteins in the lipid matrix is primarily a consequence of their hydrophobic regions residing in the lipid interior and their hydrophilic and ionic regions occupying the surface. This is thermodynamically the most stable configuration. Changes in the fluidity of the lipids alter protein conformations, which then may modulate their activity. This was one of the mechanisms of action proposed for gaseous anesthetics, although recently specific protein receptors have now been suggested. In some cases, aqueous channels form from integral proteins that traverse the membrane. In other cases, these integral proteins may actually be enzymatic transport proteins that function as active or facilitative transport systems. The primary pathway for drugs to cross these lipid membranes is by passive diffusion through the lipid environment.

Thus, in order for a drug to be absorbed or distributed throughout the body, it must be able to pass through a lipid membrane on some part of its sojourn through the body. In some absorption sites and in many capillaries, fenestrated pores exist, which allow some flow of small molecules. This is contrasted to some protected sites of the body (e.g., brain, cerebral spinal fluid) where additional membranes (e.g., glial cells) may have to be traversed before a drug arrives at its target site. These specialized membranes could be considered a general adaptation to further shelter susceptible tissues from hostile lipophilic chemicals. In this case, drug characteristics that promote transmembrane diffusion would favor drug action and effect (again unless specific transport systems intervene).

This general phenomenon of the enhanced absorption and distribution of lipophilic compounds is a unifying tenet that runs throughout the study of drug fate. The body's elimination organs can also be viewed as operating along a somewhat similar principle. The primary mechanism by which a chemical can be excreted from the body is by becoming less lipophilic and more hydrophilic, the latter property being required for excretion in the aqueous fluids of the urinary or biliary systems. When a hydrophilic or polar drug is injected into the bloodstream, it will be minimally distributed and rapidly excreted by one of these routes. However, if a compound's lipophilicity evades this easy excretion, the

Figure 2.2 Illustration of how absorption, distribution, and excretion is essentially a journey of the drug through various lipoidal membrane barriers.



liver and other organs may metabolize it to less lipophilic and more hydrophilic metabolites that have a restricted distribution (and thus reduced access to sites for activity) in the body and can be more readily excreted. This basic tenet runs throughout all aspects of pharmacology and is a useful concept to predict effects of unknown compounds.

Drug Passage Across Membranes

Considerable evidence exists that lipid-based membranes are permeable to nonpolar lipid-soluble compounds and polar water-soluble compounds with sufficient lipid solubility to diffuse through the hydrophobic regions of the membrane. The rate of diffusion of a compound across a membrane is directly proportional to its concentration gradient across the membrane, lipid\water partition coefficient, and diffusion coefficient. This can be summarized by Fick's law of diffusion in Equation 2.1:

$$\begin{array}{l}\text{Rate of}\\\text{diffusion}\\\text{(mg/ sec)}\end{array} = \frac{\text{D (cm/sec) P}}{\text{h (cm)}}\left(\text{X}_1 - \text{X}_2\right)\text{(mg)} \qquad (2.1)$$

where D is the diffusion coefficient for the specific penetrant in the membrane being studied, P is the partition coefficient for the penetrant between the membrane and the external medium, h is the thickness or actual length of the path by which the drug diffuses through the membrane, and $X_1 - X_2$ is the concentration gradient (ΔX) across the membrane. The diffusional coefficient of the drug is a function of its molecular size, molecular conformation and solubility in the membrane milieu, and degree of ionization. The partition coefficient is the relative solubility of the compound in lipid and water that reflects the ability of the penetrant to gain access to the lipid membrane. Depending on the membrane, there is a functional molecular size and/or weight cut-off that prevents very large molecules from being passively absorbed across any membrane. When the rate of a process is dependent upon a rate constant (in this case [DP/h] often referred to as the permeability coefficient P) and a concentration gradient, a linear or first-order kinetic process is evident (see Chapter 3 for full discussion). In membrane transfer studies, the total flux of drug across a membrane is dependent on the area of membrane exposed; thus the rate above is often expressed in terms of cm^2. If the lipid : water partition coefficient is too great, depending on the specific membrane, the compound may be sequestered in the membrane rather than traverse it.

Evidence also exists that membranes are more permeable to the nonionized than the ionized form of weak organic acids and bases. If the nonionized moiety has a lipid : water partition coefficient favorable for membrane penetration, it will ultimately reach equilibrium on both sides of the membrane. The ionized form of the drug is completely prevented from crossing the membrane because of its low lipid solubility. The amount of the drug in the ionized or nonionized form depends upon the pKa (negative logarithm of the acidic dissociation constant) of the drug and the pH of the medium on either side of the membrane (e.g., intracellular versus extracellular fluid; gastrointestinal versus extracellular fluid). Protonated weak acids are nonionized (e.g., COOH) while protonated weak bases are ionized (e.g., $\text{NH}_3{}^+$). If the drug has a fixed charge at all pHs encountered inside and outside of the body (e.g., quarternary amines, aminoglycoside antibiotics), they will never cross lipid membranes by diffusion. This would restrict both their absorption and distribution and generally lead to an enhanced rate of elimination. It is the nonionized form of the drug that is governed by Fick's Law of Diffusion and described by Equation 2.1 above. For this equation to predict the movement of a drug across membrane systems in vivo, the relevant pH of each compartment must be considered relative to the compound's pKa; otherwise, erroneous predictions will be made.

When the pH of the medium is equal to the pKa of the dissolved drug, 50% of the drug exists in the ionized state and 50% in the nonionized, lipid-soluble state. The ratio of nonionized to ionized drug is given by the Henderson–Hasselbalch equation (Equations 2.2 and 2.3).For acids:

$$\text{pKa} - \text{pH} = \log\left[(\text{HAcid})^0/(\text{HAcid})^-\right] \qquad (2.2)$$

For bases:

$$\text{pKa} - \text{pH} = \log\left[(\text{H Base})^+/(\text{H Base})^0\right] \qquad (2.3)$$

These equations are identical as they involve the ratio of protonated (H) to nonprotonated moieties. The only difference is that for an acid, the protonated form $(\text{H Acid})^0$ is neutral while for a base, the protonated form $(\text{H Base})^+$ is ionized. This topic is also presented in Chapter 5 (Equations 5.1 to 5.5; Figure 5.3).

As can be seen by these equations, when the pH is one unit less or one unit more than the pKa for weak bases or acids, respectively, the ratio of ionized to nonionized is 10. Thus each unit of pH away from the pKa results in a tenfold change in this ratio. This phenomenon allows for a drug to be differentially distributed across a membrane in the presence of a pH gradient, an effect that often dwarfs that obtainable by increasing dose to increase drug delivery to a specific tissue. The side of the membrane with the pH favoring ionized drug (high pH for an acidic drug; low pH for an alkaline drug) will tend to have higher total (ionized plus nonionized) drug concentrations. This pH partitioning results in so-called "ion trapping" in the area where the ionized drug predominates. Figure 2.3 illustrates this concept with an organic

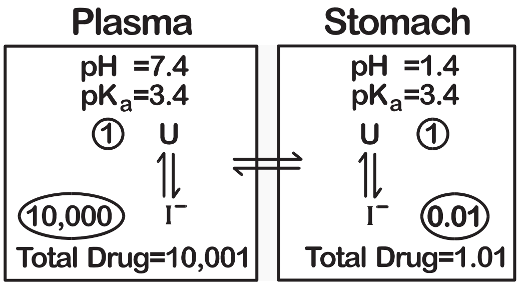


Figure 2.3 The phenomenon of pH partitioning and ion trapping of a weak acid.

acid of pKa = 3.4 partitioning between gastric contents of pH = 1.4 and plasma of pH = 7.4. Assuming that the nonionized form of the drug (U) is in equilibrium across the membrane, then, according to Equations 2.1 and 2.2, there will be a 100-fold (log 2; 3.4–1.4) difference on the gastric side and a 10,000-fold (log 4; 7.4–3.4) difference on the plasma side of the membrane, for a transmembrane concentration gradient of total drug (U plus I) equal to 10,001/1.01. Note that the unionized concentration on both sides of the membrane are in equilibrium. It is the total drug concentrations that are different. In this case, the gradient is generated by the difference in pH across an ion-impermeable barrier generated by the local milieu.

Such a gradient would greatly favor the absorption of this weak acid across the gastrointestinal tract into plasma. This is the situation that exists for weak acids such as penicillin, aspirin, and phenylbutazone. In contrast, a weak base would tend to be trapped in this environment and thus minimal absorption would occur. Examples of such weak bases are morphine, phenothiazine, and ketamine. Specific active transport systems may counter these predictions (e.g., β-lactam transporters in intestines), as well as the extreme surface area of the small intestines compared to gastric mucosa, which generally favors absorption of most drugs in the small intestines. With the weakly basic strychnine, pH-dependent absorption is toxicologically significant. If strychnine were placed into the strongly acidic stomach, no systemic toxicity would be observed. However, if the stomach were then infused with alkali, most of this base would become nonionized, readily absorbed, and lethal. In summary, weak acids are readily absorbed from an acid environment and sequestered in an alkaline medium. In contrast, weak bases are absorbed in an alkaline environment and trapped in an acidic environment.

This pH partitioning phenomenon is not only important in understanding absorption (as illustrated above), but also in any situation where the pH of fluid compartments across a biological membrane is different. It will occur for a drug distributing from plasma (pH = 7.4) to milk (pH = 6.5–6.8), to cerebrospinal fluid (pH = 7.3), or to intracellular sites (pH = 7.0). Thus weakly acidic drugs will tend not to distribute into the milk after systemic distribution (e.g., penicillin), while weakly basic drugs (e.g., erythromycin) will. If a disease process alters the pH of one compartment (e.g., mastitis), the normal equilibrium ratio will also be perturbed. In mastitis, where pH may increase almost one unit, this preferential distribution of basic antibiotics will be lost. The relatively acidic pH of cells relative to plasma is responsible for the relatively large tissue distribution seen with many weakly basic drugs (e.g., morphine, amphetamine). Similarly, in the ruminant, many basic drugs tend to distribute into the rumen, resulting in distribution volumes much larger than those in monogastrics. In fact, a drug that distributes into this organ may then undergo microbial degradation resulting in its elimination from the body.

This phenomenon is also very important for the passive tubular reabsorption of weak acids and bases being excreted by the kidney. For carnivores with acidic urine relative to plasma, weak acids tend to be reabsorbed from the tubules into the plasma while weak bases tend to be preferentially excreted. This principle has been applied to the treatment of salicylate (weak acid) intoxication in dogs where alkaline diuresis promotes ion trapping of the drug in the urine and hence its rapid excretion. Disease-induced changes in urine pH will likewise alter the disposition of drugs sensitive to this phenomenon.

Movement across the fenestrated capillaries of the body from plasma to tissue areas generally allows movement of most drugs. In these cases, relatively small molecules (molecular weights <1,000) can pass through independent of their lipid solubility, but larger molecules are excluded. In all of these scenarios, drugs move through these tissues as a solute dissolved in water and essentially are transported wherever the water goes. This process is termed *bulk flow* and is dependent on the concentration of drug dissolved in the plasma or tissue fluid. This is a linear process and thus is easily modeled by most pharmacokinetic systems. It is the subsequent uptake into cells and special tissue areas that are governed by the diffusion processes above.

There exist several specialized membranes that possess specific transport systems. In these cases, the laws of diffusion and pH partitioning do not govern transmembrane flux of drugs. These specializations in transport can best be appreciated as mechanisms by which the body can exert control and selectivity over the chemicals that are allowed to enter the protected domain of specific organs, cells, or organelles. Such transport systems can be rather nonspecific, as are those of the kidney and liver that excrete charged waste products.

In the gastrointestinal tract, relatively nonspecific transport systems allow for the absorption, and thus entrance to the body, of essential nutrients that do not have sufficient lipophilicity to cross membranes by diffusion. In specific tissues, they allow for select molecules to enter cells depending upon cellular needs, or allow compounds that circulate throughout the body to have a biological response only in a tissue possessing the correct transport receptor. The primary example is the protein carrier-mediated processes of active transport or facilitated diffusion. These systems are characterized by specificity and saturability. In the case of active transport, biological energy is utilized to move a drug against its concentration gradient. In facilitated diffusion, the carrier protein binds to the drug and carries it across the membrane down its concentration gradient. The drugs transported by these systems normally cannot cross the membrane by passive diffusion because they are not lipophilic. These systems are important for the gastrointestinal absorption of many essential nutrients and some drugs (e.g., β-lactams), for cellular uptake of many compounds (e.g., glucose), for the removal of drugs from the cerebral spinal fluid through the choroid plexus, and for biliary and renal excretion of numerous drugs.

In some tissues, cells may absorb drugs by endocytosis or pinocytosis, processes where a compound binds to the surface of the membrane that then invaginates and interiorizes the compound. This is not a primary mechanism of transmembrane passage for most therapeutic drugs. It is the primary mechanism by which nanomaterials enter cells. Most inorganic ions such as sodium and chloride are sufficiently small that they easily can cross aqueous pores and channels through membranes. The movement of these charged substances is generally governed by the transmembrane electrical potential maintained by active ion pumps.

Finally, active transport may also occur in the opposite direction to remove a drug after it has been absorbed into specific cells or tissue sites. This is called the *P-glycoprotein system,* a class of drug transporters originally associated with multiple drug resistance (MDR) encountered in cancer chemotherapy. MDR transporters have been identified in intestinal epithelial cells, the placenta, kidney tubules, brain endothelial cells, and liver bile canaliculus. These will be addressed throughout this text for specific drug classes.

In conclusion, an understanding of the processes that govern the movement of drugs across lipid-based biological membranes is important to the study of drug absorption, distribution, and excretion. Lipid-soluble drugs are easily absorbed into the body and well distributed throughout the tissues. In contrast, hydrophilic drugs are not well absorbed and have limited distribution but are easily eliminated. Metabolism converts lipophilic drugs to more easily excreted hydrophilic entities. If membranes separate areas of different pH, concentration gradients may form due to pH partitioning or ion trapping. Membranes are the building blocks of biological systems and play a central role in defining the complexity of pharmacokinetic models.

Absorption

Absorption is the movement of the drug from the site of administration into the blood. There are a number of methods available for administering drugs to animals. The primary routes of drug absorption from environmental exposure in mammals are gastrointestinal, dermal, and respiratory. The first two are also used as routes of drug administration for systemic effects, with additional routes including intravenous, intramuscular, subcutaneous, or intraperitoneal injection. Other variations on gastrointestinal absorption include intraruminal, sublingual, and rectal drug delivery. Many techniques are also used for localized therapy, which may also result in systemic drug absorption as a side effect. These include, among others: topical, intramammary, intraarticular, subconjunctival, and spinal fluid injections. Methods of utilizing these different routes of drug administration are also explored in Chapter 5.

Gastrointestinal Absorption

One of the primary routes of drug administration is oral ingestion of a pill or tablet that is designed to deliver a drug across the gastrointestinal mucosa. The common factor in all forms of oral drug administration is a method to deliver a drug such that it gets into solution in the gastrointestinal fluids from which it can then be absorbed across the mucosa and ultimately reach the submucosal capillaries and the systemic circulation. Examples of oral drug delivery systems include solutions (aqueous, elixirs) and suspensions, pills, tablets, boluses for food animals, capsules, pellets, and sustained release mechanical devices for ruminants. The major obstacle encountered in comparative and veterinary medicine is the enormous interspecies diversity in comparative gastrointestinal anatomy and physiology, which results in major species differences in strategies for and efficiency of oral drug administration. This is often appreciated but overlooked when laboratory animal data is extrapolated to humans. Rats and rabbits are widely utilized in preclinical disposition and toxicology studies, although many investigators fail to appreciate that these species' gastrointestinal tracts are very different from one another and from humans.

From a pharmacologist's perspective, the gastrointestinal tract of all species can be simply presented as diagrammed in Figure 2.4. The GI tract is best conceptualized as actually being part of the external environment, which, in contrast to the skin, is protected and whose

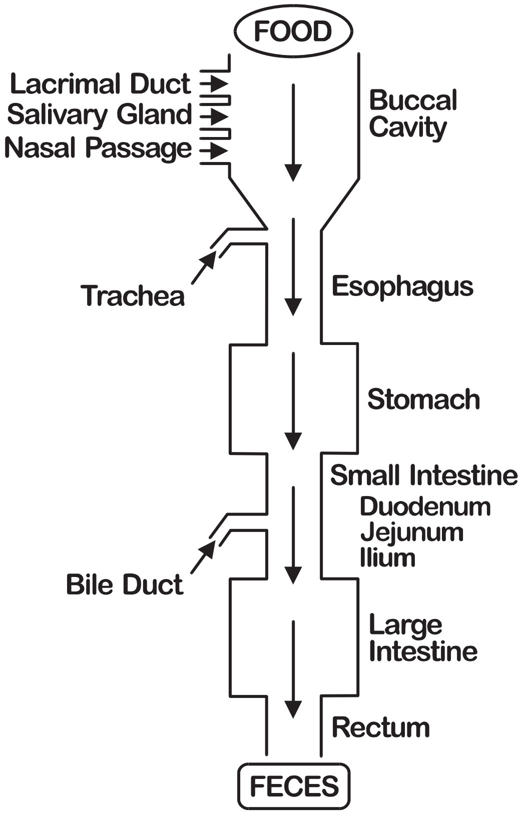

Figure 2.4 Functional structure of the gastrointestinal tract.

microenvironment is closely regulated by the organism. Because of the gastrointestinal tract's central role in digestion and nutrient absorption, there are many evolutionary adaptations to this basically simple mucosa structure that allow for physical, chemical, enzymatic, and microbial breakdown of food for liberation and ultimate absorption of nutrients. This tract is further adapted such that these digestive processes do not harm the organism's own tissues, which in carnivores may be identical to the food being eaten.

The gastrointestinal tract presents a significant degree of heterogeneity relative to morphology and physiology that translates to great regional variations in drug absorption. In the oral cavity, where food is masticated, some absorption may occur in sublingual areas. In fact, this site is actually utilized as a route for systemic drug (e.g., nitroglycerin) and nicotine (e.g., oral tobacco) delivery in humans. The esophagus and cranial portion of the stomach is lined by cornified epithelium, which provides an effective barrier that often decreases the chance of absorption for drugs formulated for intestinal drug delivery. A great deal of recent research activity has been focused on developing new transbuccal drug delivery systems. As mentioned, the prototype example was sublingual nitroglycerin tablets. Newer systems use novel adhesive technology, which allow actual polymer patches to adhere to the buccal mucosa. Such products are also being considered for some therapeutic applications in veterinary medicine (e.g., feline oral sprays). Compared to oral gastrointestinal absorption, buccal delivery bypasses the portal vein and thus eliminates the potential for first-pass hepatic biotransformation, discussed later.

The simple mucosal lining of the stomach allows absorption; however, the presence of surface mucus, which protects the epithelium from self-digestion secondary to acid and enzyme secretion, may be a barrier for some drugs. The acidity and motility of the stomach also creates a hostile environment for drugs and even influences the absorption of drugs farther down the tract. For oral drug absorption to be successful, the drug must be capable of surviving this relatively harsh environment. For some drugs (e.g., penicillin G) susceptible to acid hydrolysis, minimal absorption by the oral route will occur unless they are administered in a formulation that protects them in an acid environment but liberates them in the more alkaline environment of the intestines. Release of the drug from the stomach, a process controlled by gastric emptying, is a major rate-determining step in the onset and duration of oral drug activity. Species differences in the size of the pyloric orifice also limit use of some dosage forms in small animals versus humans.

The primary site for most drug absorption is the small intestine. In this region of the gastrointestinal tract, the pH of the contents are more alkaline and the epithelial lining is conducive to drug absorption. The blood flow to this region is also much greater than to the stomach. The small intestine is lined by simple columnar epithelium resting on a basement membrane and a submucosal tissue bed that is very well perfused by an extensive capillary and lymphatic network. This capillary bed drains into the hepatic portal vein. One of the major anatomical adaptations for absorption in this region is the presence of microvilli, which increase the surface area of the small intestine some 600-fold over that of a simple tube. The second anatomical adaptation are the villi of the intestine, which can be easily appreciated by examining a cross section (Figure 2.5). Since diffusion is the primary mechanism for drug absorption, the increase in area due to these two anatomical configurations significantly increases absorption, as can be seen from reviewing the area contribution to Equation 2.1. There are species differences in inherent permeability of the intestinal mucosa to chemicals, with the dog recently being recognized as having a higher permeability to many drugs than humans.

The viable epithelial cells of the intestines are also endowed with the necessary enzymes for drug metabolism that contributes to a second "first-pass" effect. Recent research has also indicated that the mechanism and extent of absorption, and magnitude of local

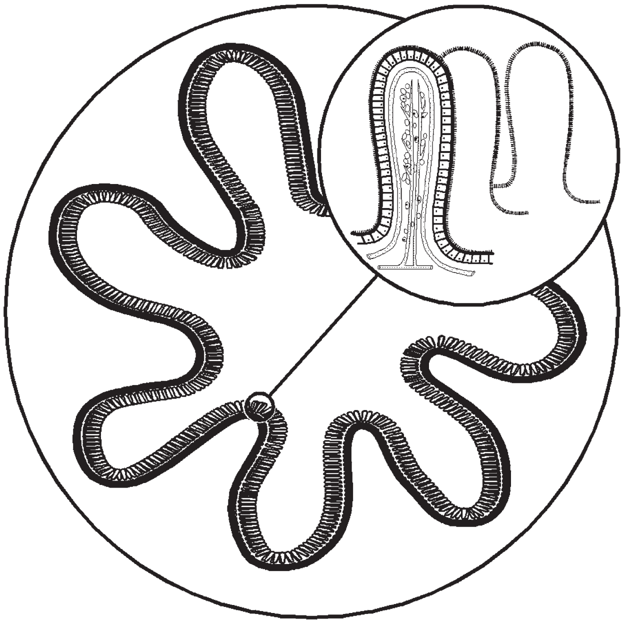

Figure 2.5 Cross-section of the small intestine showing villi adaptations, which serve to increase surface area available for absorption.

intestinal metabolism, varies between the tips and crypts of the villi. The final determinant of a drug's tortuous journey through the gastrointestinal tract is the resident microbial population that inhabits the intestinal contents. Many bacteria are capable of metabolizing specific drugs, resulting in a third component of the first-pass effect. This epithelial and bacterial biotransformation is generally categorized as *presystemic* metabolism to differentiate it from that which occurs following portal vein delivery of drug to the liver. However, from the perspective of pharmacokinetic analysis of plasma drug concentrations following oral drug administration, all three components are indistinguishable and become lumped into the aggregate process of oral absorption assessed as K_a.

Disintegration, Dissolution, Diffusion, and Other Transport Phenomenon

In order for a drug to be absorbed across the intestinal mucosa, the drug must first be dissolved in the aqueous intestinal fluid. Two steps, disintegration and dissolution, may be required for this to occur. *Disintegration* is the process whereby a solid dosage form (e.g., tablet) physically disperses so that its constituent particles can be exposed to the gastrointestinal fluid. Dissolution occurs when the drug molecules then enter into solution. This component of the process is technically termed the *pharmaceutical phase* and is controlled by the interaction of the formulation with the intestinal contents. These concepts are further elaborated on in Chapter 5.

Some dosage forms, such as capsules and lozenges, may not be designed to disintegrate, but rather to allow a drug to slowly elute from their surface. Dissolution is often the rate-limiting step controlling the absorption process and can be enhanced by formulating the drug in salt form (e.g., sodium or hydrochloride salts), buffering the preparation (e.g., buffered aspirin), or decreasing dispersed particle size (micronization) so as to maximize exposed surface area. This is extensively discussed in Chapter 5 (see equation 5.7). Alternatively, disintegration and dissolution can be decreased so as to deliberately provide slow release of the drug. This strategy is used in *prolonged-release* or *controlled-release* dosage forms and involves complex pharmaceutical formulations that produce different rates of dissolution. This may be accomplished by dispersing the dosage form into particles with different rates of dissolution or by using multilaminated dosage forms, which delays release of the drug until its layer is exposed. All of these strategies decrease the overall rate of absorption. Similar strategies can also be used to target drugs to the distal segments of the gastrointestinal tract by using enteric coatings that dissolve only at specific pH ranges, thereby preventing dissolution until the drug is in the region targeted. This strategy has been applied for colonic delivery of drugs in humans for treatment of Crohn's disease.

In slow-release or long-acting formulations, the end result is that absorption becomes slower than all other distribution and elimination processes, making the pharmaceutical phase the rate-limiting or rate-controlling step in the subsequent absorption and disposition of the drug. When this occurs, as will be seen in the pharmacokinetic modeling chapters to follow, the rate of absorption controls the rate of apparent drug elimination from the body and a so-called *flip-flop* scenario becomes operative.

There are significant species differences in the ability to use controlled-release oral medications designed in humans, by far the largest market, in other species. The first limitation involves the inability to use cellulose-based systems in ruminants due to the ability of rumen microbes to digest the normally inert cellulose matrix that controls rates of drug delivery. The second arises because of shorter gastrointestinal transit times in small carnivores, such as domestic cats and dogs, compared to humans. In this instance, drug release is designed to occur in the longer transit times seen in humans (approx. 24 hours). In dogs and cats, which have transit times half that of humans, drug release may still be occurring even after the tablet has been eliminated in the feces due to the shorter transit times. Other examples include the narrower pyloric opening in dogs, compared to humans, that may increase gastric retention of some larger dosage forms. These are but a few examples of significant species differences that, based on anatomical and physiological factors, prevent the ready transferability of complex dosage forms across species.

After the drug is in solution, it must still be in a nonionized relatively lipid-soluble form to be absorbed across the lipid membranes comprising the intestinal mucosa. *It must be stressed that absorption across any membrane is a fine balance between adequate solubility on the donor side of the membrane with sufficient permeability (or active transport capacity) to actually transit the membrane.* For orally administered products, the pH of the gastrointestinal contents becomes very important, as is evident from the earlier discussion on pH partitioning. Specifically, a weak acid would tend to be preferentially absorbed in the more acidic environment of the stomach since a larger fraction would be in the nonionized form. However, the much larger surface area and blood flow available for absorption in the more alkaline intestine may override this effect. It is important to mention at this point why a weak acid such as aspirin is better absorbed in a bicarbonate buffered form, which would tend to increase the ionized fraction and thus decrease membrane passage. The paradox is that dissolution must first occur, a process favored by the ionized form of the drug. It is only the dissolved ionized aspirin that is available to the partitioning phenomenon described earlier. Thus, when more aspirin is dissolved in the buffered microenvironment, more is available for partitioning and diffusion across the mucosa. In contrast to the situation of a weak acid, a weak base would tend to be better absorbed in the more alkaline environment. However, it must be repeated that the very large surface area available in the intestines, coupled with high blood flow and a pH of approximately 5.3 in the immediate area of the mucosal surface makes it the primary site of absorption for most drugs (weak acids with pKa >3 and weak bases with pKa <7.8). Species differences in both gastric and intestinal pH further modulate this differential (e.g., canine gastric pH is much higher than humans). A further obstacle to absorption is that the compound must also be structurally stable against chemical or enzymatic attack. Finally, compounds with a fixed charge and/or very low (or very high) lipid solubility for the uncharged moiety, may not be significantly absorbed after oral administration. Examples include the polar aminoglycoside antibiotics, the so-called "enteric" sulfonamides, and quaternary ammonium drugs.

There are also specific active transport systems present within the intestinal mucosa of the microvilli that are responsible for nutrient absorption. However, these systems have a very high capacity and if a specific drug or toxicant has the proper molecular configuration to be transported, saturation is unlikely. There is some evidence that select therapeutic drugs (e.g., β-lactams such as ampicillin) may be absorbed by active transport systems in the small intestine. There are also transport systems (P-glycoprotein) that expel absorbed drug back into the intestinal lumen. This system is beginning to be studied more closely in veterinary species and will be discussed later in this chapter under distribution and elimination.

The complexity of these processes is clearly seen when one tries to extrapolate oral bioavailability of drugs between dogs and humans. In order to try and classify drug absorption in humans based on criteria of solubility and permeability, the Biopharmaceutical Classification System (BCS) was developed, which ranked drugs according to their extent and rate of absorption, with Class I drugs being both highly soluble and permeable resulting in generally very well absorbed compounds, in contrast to Class IV which had low solubility and low permeability and showed very poor oral absorption. Class II and III have mixed solubility and permeability characteristics. The advantage of such classifications is that manufactures changing formulations for Class I drugs only need to conduct in vitro dissolution studies since dissolution would be the rate-limiting process in absorption. Class IV drugs would require in vivo comparisons. Drugs classified using this system for humans did not correlate to what was observed in dogs, suggesting that the differences in GI physiology discussed above prevents easy interspecies extrapolations (Papich and Martinez, 2015).

Enterohepatic Recycling and Coprophagy

The gastrointestinal tract has also evolved into an excretory organ for elimination of nonabsorbed solid wastes and other metabolic byproducts excreted in the bile. The bile duct drains into the upper small intestine. For some drugs, this results in a phenomenon called *enterohepatic recycling* whereby a drug from the systemic circulation is excreted into the bile and is reabsorbed from the small intestine back into the bloodstream. In many cases, drugs that are metabolized by Phase II conjugation reactions are "unconjugated" by resident bacterial flora, which generates free drug for reabsorption. Thus compounds that are excreted into the bile may have a prolonged sojourn in the body because of the continuous opportunity for intestinal reabsorption. The cardinal sign of this process is a "hump" in the plasma drug concentration-time profile after administration (Figure 2.6). Bile also serves to emulsify fatty substances that are not capable of solubilizing in the primarily aqueous environment of the intestines. The result of this detergent-like action of bile is to form large surface area micelles having a hydrophilic surface and hydrophobic interior. These act as transport vehicles to deliver fat-soluble drugs to the intestinal brush border surface for diffusion across the lipid membrane into the cell. Without the interaction of bile acids, fatty substances would not be available for absorption since they could not traverse this "dissolution" barrier. Thus unlike most drugs, compounds that are absorbed

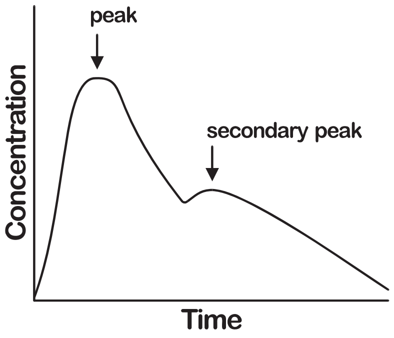

Figure 2.6 Concentration versus time profile demonstrating a secondary peak that could result from enterohepatic recycling.

by this route often must be administered with a meal to promote bile acid secretion and associated micelle formation.

Enterohepatic recycling has also been suggested as an important mechanism for enhanced activity of certain antiparasitic drugs such as the avermectins. As discussed in Chapter 41, the recycling of active drug is a major contributor to enhanced parasite exposure. Finally, some species such as rabbits, routinely ingest fresh feces for nutritional purposes, which provides another opportunity for drug to be reabsorbed into the body.

Species Effects on Gastrointestinal Transit Time and Food Interactions

Food may also interact with other aspects of oral drug absorption and have opposite effects for more hydrophilic drugs. Depending on the physicochemical properties of the specific drug, administration with food may significantly increase or decrease absorption. Such effects are not only drug dependent, but also are species dependent due to the continuous foraging behavior of ruminants and some other omnivores compared to the periodic feeding habits of predatory carnivores. These variables are difficult to incorporate into formal pharmacokinetic models yet they add to the variability in parameters derived from these studies or in drug response between species.

The first potential interaction relates to the rate of drug delivery to the small intestine that is governed by the rate of drug release from the stomach, the *gastric emptying time*. This process is dependent upon the eating habits of the species, with continuous foraging animals (e.g., herbivores such as horses and ruminants) having a steady input of drug and a relatively stable gastric pH compared to periodic eaters (e.g., carnivores like dogs and cats and omnivores such as pigs) who have more variable eating patterns with large swings in gastric pH depending on the presence or absence of food. In addition, the drug may directly interact with the ingested food, as is the case of chelation of tetracyclines with divalent cations such as Mg^{++} in antacids or Ca^{++} in milk products. Thus, the decision to administer a compound with or without food is species and drug dependent and may significantly alter the bioavailability (rate and extent of absorption) of the drug. In contrast, for very-lipid-soluble drugs, food is necessary in order to have bile release, which allows solubilization and absorption to occur.

The forestomachs of a ruminant provide a major obstacle to the delivery of an oral dosage form to the true stomach (abomasum) for ultimate release to the intestines, although a significant amount of drug absorption may occur from this site. The rumen is essentially a large fermentation vat (>50 liters in cattle, 5 liters in sheep) lined by stratified squamous epithelium, buffered at approximately a pH of 6 by extensive input of saliva, which maintains it in a fluid to soft consistency, designed primarily for the absorption of volatile fatty acids. If drugs dissolve in this medium and remain intact, they undergo tremendous dilution that decreases their rate of absorption. They then are pumped from the rumen and reticulum through the omasum for a rather steady input of drug into the true stomach. An understanding of the physiology of the ruminant has allowed for the development of some unique and innovative mechanical drug delivery technologies, which essentially are encapsulated pumps that “sink” to the bottom of the rumen and become trapped, much as many unwanted objects tend to when ingested by a ruminant (e.g., nails and wire in hardware disease). These “submarine-like” devices then slowly release drug into the ruminal fluid for a true sustained-release preparation. In preruminant calves, a drug may bypass the rumen entirely through the rumen-reticulo groove and essentially behave as if administered to a monogastric. In contrast, fermentation in the horse occurs after drug absorption by the small intestine and thus has less impact than in ruminants. However, a nonabsorbed drug that reaches the equine large intestines and cecum, the site of fermentation, may have disastrous effects (e.g., colic) if digestive flora or function is perturbed.

First-Pass Metabolism

Another unique aspect of oral drug absorption is the fate of the absorbed drug once it enters the submucosal capillaries. Drug absorbed distal to the oral cavity and proximal to the rectum in most species enters the portal circulation and is transported directly to the liver where biotransformation may occur. This is a major cause for differences in a drug’s ultimate disposition compared to all other routes of administration. This may result in a significant first-pass biotransformation of the absorbed compound. For a drug that is extensively metabolized by the liver, this first-pass effect significantly reduces absorption of the active drug even when it is absorbed across the mucosa. This occurs for many opiate medications in dogs, reducing their efficacy after oral administration. Finally, some drugs that are too polar to be absorbed across the gastrointestinal wall are formulated as ester conjugates to increase lipid solubility and enhance absorption. Once the drug crosses the gastrointestinal epithelium in this form, subsequent first-pass hepatic biotransformation enzymes and circulating blood and mucosal esterases cleave off the ester moiety releasing free drug into the systemic circulation.

There are selected drug administration sites that avoid first-pass hepatic metabolism by allowing absorption through gastrointestinal tract segments *not* drained by the portal vein. These include the oral cavity buccal and rectal routes of drug administration in some species, although this assumption hasn't been tested in many veterinary species.

Formulation Factors

The pharmaceutical literature is replete with formulation factors that may influence the dissolution and absorption of a drug preparation, assuming in the first place that one has an active component of known purity and potency. These are fully discussed in Chapter 5. The issue then becomes what are the potential interactions that can occur between the active ingredients and the excipients that make up the formulation. Additionally, what are the effects of the practitioner's compounding techniques (materials used, mixing efficacy, etc.) on the amount of active ingredients ultimately appearing in the formulation. Although this discussion is the focus of a biopharmaceutics text, the strategies are often encountered in pharmacokinetics as they may affect the parameters estimated after oral administration.

Table 2.1 depicts the pharmaceutical processes involved in absorption that may be affected by formulation. Following oral administration of tablets, disintegration must first occur. The speed and efficacy of this process will determine how much drug is actually available for subsequent steps. The resulting particle size (and hence surface area) is an important determinant for the next dissolution phase where the drug enters solution, an absolute prerequisite for diffusion across the mucosal barrier. Dissolution also involves diffusion across the liquid boundary layers that are an interface between the particles and the absorption milieu. Many pharmaceutical factors may affect the efficiency of the disintegration and dissolution processes. For tablets, the nature and homogeneity of the excipients become important considerations. These factors are the primary determinants of differences in efficacy between so-called "pioneer" and generic drug products. Once the drug is in solution, binding or complexation to inert filler ingredients may occur. It is important to remember that all of this is happening while the particles are in transit through the gastrointestinal tract. Thus, if the formulation results in a decreased rate of disintegration or dissolution, the rate and extent of absorption may be decreased, especially in species with very short gastrointestinal transit times. Similar factors are involved with oral capsules and even liquid dosage forms where the drug may interact with the vehicle. In fact, these scenarios are probably most pertinent to practitioner compounding. For capsules, the breakdown of the capsule replaces tablet disintegration as the initial rate-determining step. After release of the capsule contents, all of the above factors come into play. It cannot be overstated that such pharmaceutical factors are critical determinants of the extent and rate of subsequent drug absorption.

Topical and Percutaneous Absorption

The skin is a complex, multilayered tissue comprising 18,000 cm^2 of surface in an average human male. The quantitative prediction of the rate and extent of percutaneous penetration (into skin) and absorption (through skin) of topically applied chemicals is complicated by the biological variability inherent in skin. Mammalian skin is a dynamic organ with a myriad of biological functions. The most obvious is its barrier property that is of primary concern in the absorption problem. Another major function is thermoregulation that is achieved and regulated by three mechanisms in skin: thermal insulation provided by pelage and hair, sweating, and alteration of cutaneous blood flow. Other functions of skin include mechanical support, neurosensory reception, endocrinology, immunology, and glandular secretion. These additional biological roles lead to functional and structural adaptations that affect the skin's barrier properties and thus the rate and extent of percutaneous absorption. Many of the topics discussed below are fully developed in Chapter 47 of this text.

The skin is generally considered to be an efficient barrier preventing absorption (and thus systemic exposure) of most topically administered compounds. It is a membrane that is relatively impermeable to aqueous solutions and most ions. It is, however, permeable in varying

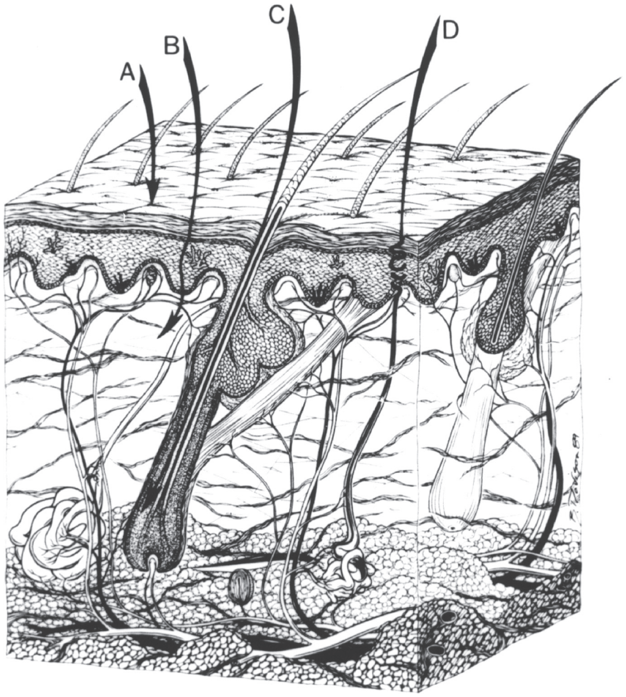

Figure 2.7 Microstructure of mammalian skin showing potential routes of penetration (A) intercellular, (B) transcellular, (C) intrafollicular, (D) via sweat ducts.

degrees to a large number of solid, liquid, and gaseous xenobiotics. Although one tends to think of most cases of poisoning as occurring through the oral or, less frequently, the respiratory route, the widespread use of organic chemicals has enhanced risk exposure to many toxicants that can penetrate the dermal barrier.

The gross features of mammalian skin are illustrated in Figure 2.7. Compared to most routes of drug absorption, the skin is by far the most diverse across species (e.g., sheep versus pig) and body sites (e.g., human forearm versus scalp). Three distinct layers and a number of associated appendages make up this nonhomogenous organ. The epidermis is a multilayered tissue varying in thickness in humans from 0.15 mm (eyelids) to 0.8 mm (palms). The primary cell type found in the epidermis is the keratinocyte. Proliferative layers of the basal keratinocyte (stratum germinativum) differentiate and gradually replace the surface cells (stratum corneum) as they deteriorate and are sloughed from the epidermis. A number of other cell types are also found interspersed in the epidermis including the pigmented melanocytes, Merkel cells which may play a sensory role, and Langerhans cells which probably play a role in cutaneous immunology.

In respect to drug penetration, the primary biochemical change is the production of fibrous, insoluble keratin that fills the cells, and a sulfur-rich amorphous protein that comprises the cell matrix and thickened cell membrane. In addition, the keratinocytes synthesize a variety of lipids that form the distinguishing granules in the stratum granulosum that release their contents into the intercellular spaces. The end result in the stratum corneum is dead proteinaceous keratinocytes embedded in an extracellular lipid matrix, a structure referred to by Elias as the “brick and mortar” model (see Figures 47.3 and 47.4).

The Stratum Corneum Barrier

It is this outermost layer, the stratum corneum, which provides the primary barrier to the penetration of foreign compounds. This barrier consists of flattened, stratified, highly keratinized cells embedded in a lipid matrix composed primarily of sterols, other neutral lipids, and ceramides. Although highly water retarding, the dead, keratinized cells are highly water absorbent (hydrophilic), a property that keeps the skin supple and soft. A natural oil covering the skin, the sebum, especially present in some species such as sheep, appears to maintain the water-holding capacity of the epidermis but has no appreciable role in retarding the penetration of xenobiotics. Disruption of the stratum corneum removes all but a superficial deterrent to penetration.

Dermis and Appendages

The dermis is a highly vascular area, providing ready access for drug distribution once the epithelial barrier has been passed. The blood supply in the dermis is under complex, interacting neural and local humoral influences whose temperature-regulating function can have an effect on distribution by altering blood supply to this area. The absorption of a chemical possessing vasoactive properties would be affected through its action on the dermal vasculature; vasoconstriction would retard absorption and increase the size of a dermal depot, while vasodilation may enhance absorption and minimize any local dermal depot formation.

The appendages of the skin are found in the dermis and extend through the epidermis. The primary appendages are the sweat glands (eccrine and apocrine), hair, and sebaceous glands, all of which show great interspecies and interregional variability. Since these structures extend to the outer surface, they potentially play a role in the penetration of certain compounds.

Topical Drug Delivery and the Definition of Dose

From the perspective of pharmacokinetic models of transdermal and topical drug delivery systems, there are significant differences from other routes of administration (e.g., oral, injection) as to what constitutes a dose. For most exposures, the concentration applied to the surface of the skin exceeds the absorption capacity. However, for therapeutic transdermal patches with a fixed concentration of the drug and rate-controlled release properties, it is the contact surface area that more accurately reflects dose and thus dose is expressed not in mg/kg, but mg/cm^2 of dosing area. This surface area dependence also holds for any topical application even if absorption capacity is superseded. Yet, another source of nonlinearity results secondary to the effects of occlusive (water-impermeable) drug vehicles or patches. As the skin hydrates, a threshold is reached where transdermal flux dramatically increases (approximately 80% relative humidity). When the skin becomes completely hydrated under occlusive conditions, flux can be dramatically increased. Therefore, dose alone is often not a sufficient metric to describe topical doses, and application method and surface area become controlling factors.

Pathways for Dermal Absorption

Anatomically, percutaneous absorption might occur through several routes. The current consensus is that the majority of nonionized, lipid-soluble toxicants appear to move through the intercellular lipid pathway between the cells of the stratum corneum, the rate-limiting barrier of the skin. Very small and/or polar molecules appear to have more favorable penetration through appendages or other diffusion shunts, but only a small fraction of drugs are represented by these molecules. Simple diffusion seems to account for penetration through the skin whether by gases, ions, or nonelectrolytes.

The rate of percutaneous absorption through this intercellular lipid pathway is correlated to the partition coefficient of the penetrant. This has resulted in numerous studies correlating the extent of percutaneous absorption with a drug's lipid : water partition coefficient. Some workers further correlated skin penetration to molecular size and other indices of potential interaction between the penetrating molecule and the skin that are not reflected in the partition coefficient. For most purposes, however, dermal penetration is often correlated to partition coefficient. If lipid solubility is too great, compounds that penetrate the stratum corneum may remain there and form a reservoir. Alternatively, penetrated compounds may also form a reservoir in the dermis. For such compounds, slow release from these depots may result in a prolonged absorption half-life. Conditions that alter the composition of the lipid (harsh delipidizing solvents, dietary lipid restrictions, disease) may alter the rate of compound penetration by changing its partitioning behavior. Very similar to the situation with oral absorption previously discussed, the actual utility of a topical drug is a delicate balance between solubility and permeability which topical drug formulators attempt to exploit. Some of these concepts are further discussed in Chapters 5 and 47.

Recent studies have demonstrated that the skin may also be responsible for metabolizing topically applied compounds. Both Phase I and II metabolic pathways have been identified. For some compounds, the extent of cutaneous metabolism influences the overall fraction of a topically applied compound that is absorbed, making this process function as an alternate absorption pathway. Cutaneous biotransformation is used to promote the absorption of some topical drugs that normally would not penetrate the skin. Cutaneous metabolism may be important for certain aspects of skin toxicology when nontoxic parent compounds are bioactivated within the epidermis, for example benzo(a)pyrene to an epoxide. Finally, resident bacteria on the surface of the skin may also metabolize topical drugs, as was demonstrated with pentochlorophenol absorption in pig skin dosed in soil with and without antibiotics. This effect is potentiated under warm and wet occlusive dosing conditions that both promote bacterial growth and reduce skin barrier properties.

Variations in Species and Body Region

Penetration of drugs through different body regions varies. In humans, generally the rate of penetration of most nonionized toxicants is in the following order: scrotal > forehead > axilla = scalp > back = abdomen > palm and plantar. The palmar and plantar regions are highly cornified producing a much greater thickness that introduces an overall lag time in diffusion. In addition to thickness, the actual size of corneacytes and differences in hair follicle density may affect absorption of more polar molecules. Finally, differences in cutaneous blood flow that have been documented in different body regions may be an additional variable to consider in predicting the rate of percutaneous absorption. These factors are also important in animals, with the area of the inner ear known to be highly permeable and well perfused, thus an excellent site for drug absorption to occur.

Although generalizations are tenuous at best, human skin appears to be more impermeable, or at least as impermeable, as the skin of the cat, dog, rat, mouse, or guinea pig. The skin of pigs and some primates serve as useful approximation to human skin, but only after a comparison has been made for each specific substance. The major determinants of species differences are thickness, hair density, lipid composition, and cutaneous blood flow.

Factors that Modulate Absorption

Soaps and detergents are perhaps the most damaging substances routinely applied to skin. Whereas organic solvents must be applied in high concentrations to damage the skin and increase the penetration of solute through human epidermis, only 1% aqueous solutions of detergents are required to achieve the same effect. For a specific chemical, rate of penetration can be drastically modified by the solvent system used. In transdermal patches, specific chemical enhancers (e.g., solvents such as ethanol; other lipid-interacting moieties) are included in the formulation to reversibly increase skin permeability and enhance drug delivery. Alternatively, drug release is formulated to be rate limiting from the patch system (membranes, microencapsulation, etc.) so that a constant (zero-order) release from the patch occurs, thereby providing controlled drug delivery. Since patches are designed with the permeability properties of specific species in mind, care must be taken when using a patch designed for one species in another. There are a number of topical veterinary drugs routinely used to achieve long-acting systemic therapeutic endpoints in animals. These include the topical pesticides formulated as "spot-ons" and "pour-ons." These products are further discussed in Chapters 43 and 47 of this text. All of these issues have also been discussed in a comprehensive review of this topic (Riviere and Papich, 2001).

Another strategy for transdermal delivery, which has not widely been employed in veterinary medicine, is to overcome the cutaneous barrier by using electrical (iontophoresis) or ultrasonic (phonophoreses) energy, rather than the concentration gradient in diffusion, to drive drugs through the skin. These techniques hold the most promise for delivering peptides and oligonucleotide drugs that now only can be administered by injection. In these cases, dose is based on the surface area of application and the amount of energy required to actively deliver the drug across skin. In iontophoresis, this amounts to a dose being expressed in μAmps/cm^2. Formulation factors are also very different since many of the excipients used are also delivered by the applied electrical current in molar proportion to the active drug. Finally, a recent but related strategy is to use very short-duration, high-voltage electrical pulses (electroporation) to reversibly break down the stratum corneum barrier, allowing larger peptides and possibly even small proteins to be systemically delivered.

Respiratory Absorption

The third major route for systemic exposure to drugs and toxicants is the respiratory system. Since this system's primary function is gas exchange (O_2, CO_2), it is always in direct contact with environmental air as an unavoidable part of breathing. A number of toxicants are in gaseous (CO, NO_2, formaldehyde), vapor (benzene, CCl_4), or aerosol (lead from automobile exhaust, silica, asbestos) forms and are potential candidates for entry via the respiratory system. There are no approved inhalational drugs for use in veterinary medicine. Each mode of inhalational exposure results in a different mechanism of compound absorption and for the purposes of this text, a different definition of dose. These concepts are also discussed In Chapters 11 and 48 of this text.

Opportunities for systemic absorption are excellent through the respiratory route since the cells lining the alveoli are very thin and profusely bathed by capillaries. The surface area of the lung is large (50–100 m^2), some 50 times the area of the skin. Based on these properties and the diffusion equation presented earlier (Equation 2.1), the large surface area, the small diffusion distance, and high level of blood perfusion maximize the rate and extent of passive absorption driven by gaseous diffusion.

The process of respiration involves the movement and exchange of air through several interrelated passages including the nose, mouth, pharynx, trachea, bronchi, and successive smaller airways terminating in the alveoli where gaseous exchange occurs. All of these anatomical modifications protect the internal environment of the air passages from the harsh outside environment by warming and humidifying the inspired air. The passages also provide numerous obstacles and baffles to prevent the inhalation of particulate and aerosol droplets. Thus the absorption of particulate and aerosolized liquids, such as those employed in nebulized drug therapy, is fundamentally different from that of gases. The absorption of such impacted solids and liquids along the respiratory tract has much more in common with oral and topical absorption, with the critical caveat that the precise dose of compound finally available for absorption is very difficult to determine. Great strides have been made in developing aerosol drug delivery devices for human use that take advantage of this mechanism of impaction; however, these may not be transferable to veterinary species since their efficacy is closely related to the geometry and physiology of the human respiratory tract.

Another unique aspect of respiratory exposure is the fact that the pulmonary blood circulation is in series with the systemic circulation. Thus, in contrast to cutaneous or oral exposure, compounds absorbed in the lung will enter the oxygenated pulmonary veins that drain to the systemic arterial circulation. Compared to oral administration, this reduces first-pass hepatic metabolism. However, the pulmonary circulation is adept at metabolizing peptides secondary to its role in inactivating peptide hormones.

Vapors and Gases

Since the rate of entry of vapor-phase toxicants is controlled by the alveolar ventilation rate, the toxicant is presented to the alveoli in an interrupted fashion whose frequency in humans is equal to the rate of breathing: about 20 times/min. Doses are generally discussed in terms of the partial pressure of the gas in the inspired air. Upon inhalation of a constant tension of a toxic gas, arterial plasma tension of the gas approaches its tension in the expired air. The rate of entry is then determined by the blood solubility of the toxicant. If there is a high blood : gas partition coefficient, a larger amount must be dissolved in the blood to raise the partial pressure. Gases with a high blood : gas partition coefficient require a longer period to approach the same tension in the blood as in inspired air than it takes for less soluble gases. Similarly, a longer period of time is required for blood concentrations of such a gas to be eliminated, thus prolonging detoxification.

Another important point to consider in determining how much of an inhaled gas is absorbed into the systemic circulation is the relationship of the fraction of lung ventilated compared to the fraction perfused. Increased perfusion of the lung will favor a more rapid achievement of blood–gas equilibrium. Decreased perfusion will decrease the absorption of toxicants even those that reach the alveoli. Various "ventilation/perfusion mismatches" may alter the amount of an inhaled gas that is systemically absorbed. Similarly, pulmonary diseases that thicken the alveoli or obstruct the airways may also affect overall absorption.

Aerosols and Particulates

The absorption of aerosols and particulates is affected by a number of physiological factors specifically designed to preclude access to the alveoli. The upper respiratory tract, beginning with the nose and continuing down its tubular elements, is a very efficient filtering system for excluding particulate matter (solids, liquid droplets). The parameters of air velocity and directional air changes favor impaction of particles in the upper respiratory system. Particle characteristics such as size, coagulation, sedimentation, electrical charge, and diffusion are important to retention, absorption, or expulsion of airborne particles. In addition to these characteristics, a mucous blanket propelled by ciliary action clears the tract of particles by directing them to the gastrointestinal system (via the glottis) or to the mouth for expectoration. This system is responsible for 80% of toxicant lung clearance. In addition to this mechanism, phagocytosis is very active in the respiratory tract, both coupled to the directed mucosal route and via penetration through interstitial tissues of the lung and migration to the lymph, where phagocytes may remain stored for long periods in lymph nodes. Compared to absorption in the alveoli, absorption through the upper respiratory tract is quantitatively of less importance. However, inhaled toxicants that become deposited on the mucous layer can be absorbed into the myriad of cells lining the respiratory tract and exert a direct toxicological response. This route of exposure is often used to deliver pharmaceutics by aerosol. If a compound is extremely potent, systemic effects may occur.

The end result of this extremely efficient filtering mechanism is that most inhaled drugs deposited in nasal or buccal mucous ultimately enter the gastrointestinal tract. This can best be appreciated by examining the respiratory drainages depicted in Figure 2.1. Therefore, the disposition of aerosols and particulates largely mirrors that of orally administered drugs.

Nasal administration is a preferred route for many inhalant medications in humans. In these cases, great care is made to deliver aerosols of the specific size for deposition on the nasal mucosa and upper respiratory tract. The bioavailability of these compounds is assessed using the techniques developed for other routes, although a local effect is often desired. The problems with this strategy are the attainment of an accurately delivered dose and the inactivation and binding of administered drug by the thick mucous blanket. Drugs delivered by this route usually have a wide therapeutic window and large safety index. The final point to consider relates to some specific peculiarities of nasal absorption. In the region of the olfactory epithelium, there exists a direct path for inhaled compounds to be absorbed directly into the olfactory neural tissue and central nervous system, thereby bypassing both the systemic circulation and the blood–brain barrier. The mass of drugs involved in this uptake process is very small and thus would not affect a pharmacokinetic analysis. However, this route has obvious toxicological significance and unfortunately has not been carefully studied in veterinary species.

Other Routes of Administration

In order to complete this discussion of absorption, it is important to realize that there are other extravascular drug administration routes that are often encountered. Relative to pharmacokinetic analysis, these are dealt with in the same fashion as the primary routes discussed above. The important difference is that in all cases, the barrier to absorption is less than that encountered in oral or topical delivery. Second, all of these routes involve an invasive procedure to inject drug into an internal body tissue, thereby bypassing the epithelial barriers of the skin and gastrointestinal tract.

The primary therapeutic routes of drug administration are subcutaneous (SC or SQ) and intramuscular (IM). In these cases, the total dose of drug is known and injected into tissue that is well perfused by systemic capillaries that drain into the central venous circulation. Both of these routes as well as intravenous administration are termed *parenteral* to contrast primarily with oral (*enteral)* and topical dosing, which are classified as *nonparenteral* routes of drug administration. A primary difference between these two classes is that parenteral routes bypass all of the body's defensive mechanisms. Parenteral dosage forms are manufactured under strict guidelines that eliminate microbial and particulate contamination resulting in sterile preparations that must be administered using aseptic techniques. This restriction does apply to oral or topical dosage forms. As with all methods of drug administration, there are numerous variables associated with SC and IM dosing that can be conveniently classified into pharmaceutical and biological categories.

Finally, there are other occasional routes of drug administration employed that require absorption for activity. Administration of drugs by intraperitoneal injection is often used in toxicology studies in rodents since larger volumes can be administered. Peritoneal absorption is very efficient, provided adequate "mixing" of the injection with the peritoneal fluid is achieved. The majority of drug absorbed after interperitoneal administration enters the portal vein and thus may undergo first-pass hepatic metabolism. The disposition of intraperitoneal drug thus mirrors oral administration.

Some drugs are administered by conjunctival, intravaginal, or intramammary routes. In these cases achievement of effective systemic concentrations are often not required for what is an essentially local therapeutic effect. Prolonged absorption from these sites may result in persistent tissue residues in food-producing animals if the analytical sensitivity of the monitoring assay is sufficiently low. The systemic absorption of these dosage forms is quantitated using procedures identical to those employed for other routes of administration.

Bioavailability

The final topic to consider with absorption is the assessment of the extent and rate of absorption after oral, topical, or inhalational drug administration. The extent of drug absorption is defined as absolute systemic availability and is denoted in pharmacokinetic equations as the fraction of an applied dose absorbed into the body (F). Although this topic will also be discussed extensively in Chapter 3, it is important and convenient at this juncture to introduce the basic concepts so as to complete the discussion of drug absorption. If one is estimating the extent of drug absorption by measuring the resultant concentrations in either blood or excreta, one must have an estimate of how much drug normally would be found if the entire dose were absorbed. To estimate this, an intravenous dose is required since this is the only route of administration that guarantees that 100% of the dose is systemically available ($F = 1.0$) and the pattern of disposition and metabolism can be quantitated. Parameters used to measure systemic availability are thus calculated as a ratio relative to the intravenous dose.

For most therapeutic drug studies, systemic absorption is assessed by measuring blood concentrations. The amount of drug collected after administration by the route under study is divided by that collected after intravenous administration. When drug concentrations in blood (or serum or plasma) are assayed, total absorption is assessed by measuring the area under the concentration–time curve (AUC) using the trapezoidal method. This is a geometrical technique that breaks the AUC into corresponding trapezoids based on the number of samples assayed. The terminal area beyond the last data point (a triangle) is estimated and added together with the previous trapezoidal areas. Absolute systemic availability then is calculated as in Equation 2.4:

$$\mathrm{F}\,(\%) = \frac{\mathrm{AUC}_{\mathrm{route}} \quad \mathrm{Dose}_{\mathrm{iv}}}{\mathrm{AUC}_{\mathrm{iv}} \quad \mathrm{Dose}_{\mathrm{route}}} \tag{2.4}$$

Calculation of F provides only an estimate of the extent, and not rate, of drug absorption. To calculate rate, pharmacokinetic techniques are required and presented in Chapter 3. Finally, so-called relative systemic availability may be calculated for two nonintravenous formulations where the data for the reference product is in the denominator and the test formulation in the numerator.

Distribution

A toxicant absorbed into the systemic circulation following any route of administration must reach its site of action at a high enough concentration for a sufficient period of time to elicit a biological response. Distribution processes determine this outcome. There are numerous tissues to which a chemical may be distributed, some of them capable of eliciting a pharmacological or toxicological (intended versus unintended) response while others serve only as a sink or depot for the chemical. Sinks may also be formed as a result of chemical binding to tissue or plasma proteins. The toxicological significance of such sinks is that chemicals will be distributed to, and in some cases stored in, these tissues and only slowly released back into the systemic circulation for ultimate elimination. Such tissue binding may actually protect against acute adverse effects by providing an "inert" site for toxicant localization. Storage may, however, prolong the overall residence time of a compound in the body and promote accumulation during chronic exposure, two processes that would potentiate chronic toxicity.

If the animal is a food-producing species, such tissue storage may result in residues in the edible meat products. Tissue concentrations thus become an endpoint in themselves, devoid of a biological or toxicological relevance in the tissue they are found. Their relevance is set by regulations that legally establish safe tissue tolerances or maximum residue levels for specific tissues and species. These are based upon extrapolations of safety to the consuming human population and food consumption patterns. These concepts are developed in Chapter 61.

Distribution of chemicals to peripheral tissues is dependent on four factors:

1) Physiochemical properties of the compound (pKa, lipid solubility, molecular weight)

2) Concentration gradient established between the blood and tissue
3) Ratio of blood flow to tissue mass
4) Affinity of the chemical for tissue constituents.

The physiochemical properties of the chemical are most important in determining its propensity to distribute to a specific tissue. For most molecules, distribution out of the blood into tissue is via bulk flow through the capillary pores or by simple diffusion down a concentration gradient; hence distribution is generally described by first-order rate constants. One can conceptualize distribution as "absorption" into the tissues from the blood. The complicating factors are that the driving concentration is now dependent upon blood flow, the surface area for "absorption into tissues" is dependent upon capillary density and tissue mass, the relevant partition coefficient is the blood/tissue ratio, and plasma/tissue protein binding complicates the picture. An understanding of distribution is a prerequisite to predicting pharmacological response.

Physiological Determinants of Distribution

Body fluids are distributed between three primary compartments, only one of which, vascular fluid, is thought to have an important role in the distribution of most compounds throughout the body. Human plasma amounts to about 4% of the total body weight and 53% of the total blood volume. By comparison, the interstitial tissue fluids account for 13%, and intracellular fluids 41%, of body weight. Use of recently developed microdialysis and ultrafiltration probes and catheters allow the concentration of drug to be directly monitored in the interstitial fluid and thus further open the window for pharmacokinetic analysis. The concentration that a compound may achieve in the blood following exposure depends in part upon its apparent volume of distribution. If it is distributed only in the plasma, a high concentration could be achieved in the vascular system. In contrast, the concentration would be markedly lower if the same quantity of toxicant were distributed to a larger pool including the interstitial water and/or cellular fluids.

The next major consideration is the relative blood flow to different tissues. Two factors will potentiate chemical accumulation into a tissue: high blood flow per unit mass of tissue and a large tissue mass. Tissues with a *high blood flow/mass* ratio include the *brain, heart, liver, kidney,* and *endocrine glands*. Tissues with an *intermediate ratio* include *muscle* and *skin,* while tissues with a *low ratio* (indicative of poor systemic perfusion) include *adipose tissue* and *bone*. These ratios are generalizations and some tissues may actually be categorized in two disparate groups. An excellent example is the kidney where the renal cortex receives some 25% of cardiac output and thus has a very high blood flow/mass ratio. However, the renal medulla receives only a small fraction of this blood flow and thus could be categorized in the intermediate to low group. If the affinity of the chemical for the tissue is high, it will still accumulate in poorly perfused tissues (such as fat), although it will take a long period of time to "load" or "deplete" these tissues. A relatively low blood flow/mass ratio is a major physiological explanation for depot formation.

Tissue Barriers to Distribution

Some organs have unique anatomic barriers to xenobiotic penetration. The classic and most studied example is the blood–brain barrier, which has a glial cell layer interposed between the capillary endothelium and the nervous tissue (illustrated nicely in Figure 9.4). In the schematic membrane scheme depicted in Figure 2.2, this amounts to an additional lipid membrane between the capillary and target tissue. Only nonionized lipid-soluble compounds can penetrate this barrier. Similar considerations apply to ocular, prostatic, testicular, synovial, mammary gland, and placental drug or toxicant distribution. In addition, pH partitioning phenomenon also may occur since the protected tissue (e.g., cerebrospinal fluid) may have a lower pH than the circulating blood plasma. Chemicals may also distribute into transcellular fluid compartments, which are also demarcated by an epithelial cell layer. These include cerebrospinal, intraocular, synovial, pericardial, pleural, peritoneal, and cochlear perilymph fluid compartments.

A few tissues possess selective transport mechanisms that accumulate specific chemicals against concentration gradients. For example, the blood–brain barrier possesses glucose, L-amino acid, and transferrin transporters. If the toxicant resembles an endogenous transport substrate, it may preferentially concentrate in a particular tissue. Recent work with the blood–brain barrier has demonstrated that some of these tissues also possess drug efflux transport processes that remove drug from the protected sites. Two such processes are P-glycoprotein associated with multidrug resistance (MDR) and the weak organic acid cell-to-blood efflux systems.

P-glycoprotein is a member of the so-called ATP-binding cassette proteins that include the cystic fibrosis transmembrane regulator and the sulfonyurea-sensitive ATP-dependent potassium channel. Drugs such as vinblastine, vincristine, or cyclosporine, which have the proper physiochemical characteristics (high lipophilicity) to enter the brain, do not achieve effective concentrations because of this active efflux mechanisms. This transport system has recently been shown to cause the unique breed sensitivity of Collies to ivermectin toxicity. These transporters are also responsible for decreased bioavailability of some drugs due to active pumping of absorbed drug back into the intestinal lumen. A number of drugs also inhibit P-glycoprotein transport (e.g., ketoconazole, cyclosporine), which forms the basis for some complex drug–drug interactions. Similar processes and transport systems for peptides and other compounds are also found in other organs (e.g., liver). Chapter 50 in this text should be consulted for further details on P-glycoprotein.

Plasma Protein Binding

Following entry into the circulatory system, a chemical is distributed throughout the body and may accumulate at the site of toxic action, be transferred to a storage depot, or be transported to organs that will detoxify, activate, or eliminate the compound. Although many toxicants have sufficient solubility in the aqueous component of blood to account for simple solution as a means of distribution, the primary distribution mechanism for insoluble toxicants appears to be in association with plasma proteins. Although cellular components (e.g., red blood cells) may also be responsible for transport of drugs, such transport is seldom the major route. The transport of compounds by lymph is usually of little quantitative importance for many drugs, although it may be very important in delivering some lipophilic drugs and potentially nanoparticles to select organs. Both erythrocytes and lymph can play roles in the transport of some lipophilic drugs and toxins, in some instances to an important extent.

Studies of plasma proteins have shown albumin to be particularly important in the binding of drugs. This is especially true for weak acids, with weak bases often binding to acid glycoproteins. For certain hormones, specific high-affinity transport proteins are present. Studies of toxicant binding have been more limited, but there is evidence of a significant binding/partitioning role for lipoproteins in carrying very lipophilic chemicals in the blood. In the case of most drug–protein interactions, reversible binding is established, which follows the Law of Mass Action and provides a remarkably efficient means whereby drugs can be transported to various tissues. The strength of this association may be quantitated through the use of the dissociation constant, K_{diss}. Among a group of binding sites on proteins, those with the smallest K_{diss} value for a given drug will bind it most tightly. In contrast to reversible binding seen with most therapeutic drugs, agents like cisplatin and some potentially carcinogenic metabolites that are formed from chlorinated hydrocarbons (such as CCl_4) are covalently bound to tissue proteins. In this case, there is no true distribution of the drug as there is no opportunity for dissociation.

Once a molecule binds to a plasma protein, it moves throughout the circulation until it dissociates, usually for attachment to another large molecule. Dissociation occurs when the affinity for another biomolecule or tissue component is greater than that for the plasma protein to which the toxicant was originally bound. Thus, forces of association must be strong enough to establish an initial interaction, and they must also be weak enough such that a change in the physical or chemical environment can lead to dissociation. Dissociation could occur by binding to proteins of greater affinity (lower K_{diss} values), binding with a higher concentration of proteins of lower affinity, or changes in K_{diss} with changes in ionic strength, pH, temperature, or conformational changes in the binding site induced by binding of other molecules. As long as binding is reversible, redistribution will occur whenever the concentration of one pool (i.e., blood or tissue) is diminished. Redistribution must occur when the concentration is diminished in order to reestablish equilibrium.

Proteins complex with drugs by a variety of mechanisms. Covalent binding may have a profound direct effect on an organism due to modification of an essential molecule, but it usually accounts for a minor portion of the total dose and is of no importance in further distribution of drugs since such compounds cannot dissociate. As previously mentioned, when metabolites of some compounds are covalently bound to proteins, there may be no opportunity for subsequent release of the drug apart from release upon breakdown of the protein itself. The cancer chemotherapeutic drug cisplatin covalently binds to albumin through an aquation reaction. In incubation studies, "aging" occurs after a short period of time independent of drug concentration and the majority of circulating cisplatin is covalently bound.

Noncovalent binding is of primary importance with respect to drug distribution because of the opportunities to dissociate after transport. In rare cases, the noncovalent bond may be so tight (K_{diss} extremely small) that a compound remains in the blood for very lengthy periods. For example, 3-hydroxy-2,4,4-triiodo-α-ethyl hydrocinnamic acid has a half-life of about 1 year with respect to its binding to plasma albumin. The new cephalosporin antimicrobial cefovecin similarly is approximately 97% bound in dogs and has a half-life of 5.5 days, very long for this class of drugs.

Charged drugs may be bound to plasma proteins by ionic interactions. Electrostatic attraction occurs between two oppositely charged ions on a drug and a protein. Proteins are thereby capable of binding charged metal ions. The degree of binding varies with the chemical nature of each compound and the net charge. Dissociation of ionic bonds usually occurs readily, but some members of the transition group of metals exhibit high association constants (low K_{diss} values) and exchange is slow. Ionic interactions may also contribute to binding of alkaloids with ionizable nitrogenous groups and other ionizable toxicants. Hydrogen bonds arise when a hydrogen atom, covalently bound to one electronegative atom, is "shared" to a significant degree with a second electronegative atom. As a rule, only the most electronegative atoms (O, N, and E) form stable hydrogen bonds. Protein side chains containing hydroxyl, amino, carboxyl, imidazole, and carbamyl groups can form hydrogen bonds, as can the N and O atoms of peptide bonds themselves. Hydrogen bonding plays an important role in the structural configuration of proteins and nucleic acids. Van der Waals forces produce weak interactions, which act between the nucleus of one atom and the electrons of another atom, i.e., between dipoles and induced dipoles. The attractive forces arise from slight distortions induced in the electron clouds surrounding each nucleus as two atoms are brought close together. The binding force is critically dependent upon the proximity of interacting atoms and diminishes rapidly with distance. However, when these forces are summed over a large number of interacting atoms that "fit" together spatially, they can play a significant role in determining specificity of toxicant–protein interactions. A final mechanism of binding is based on hydrophobic interactions. When two nonpolar groups come together, they exclude the water between them, and this mutual repulsion of water results in a hydrophobic interaction. The minimization of thermodynamically unfavorable contact of a polar grouping with water molecules provides the major stabilizing effect in hydrophobic interactions.

Methods for Assessing Protein Binding

A number of methods have been employed to study drug–protein interactions, including ultrafiltration, electrophoresis, equilibrium dialysis, solvent extraction, solvent partition, ultracentrifugation, spectrophotometry, and gel filtration. The most widely used techniques are ultrafiltration and equilibrium dialysis. The basic concept is that a semipermeable membrane is used, which restricts passage of protein but allows unbound drug to cross the barrier according the diffusion. Bound drug is placed on one side of the membrane and samples are collected from the protein-free side. Ultrafiltration allows rapid protein–drug separation while equilibrium dialysis requires time for the separation to occur. The fraction of free drug is then calculated based on the amount of total drug used.

Protein-binding data are frequently expressed in terms of percent of drug bound. Although useful, the limitations should be recognized, for as drug concentration is lowered, the percentage of binding increases. When a compound has a high affinity for a protein (e.g., albumin), percent binding falls sharply when the total drug concentration exceeds a certain value that saturates the binding sites available.

Displacement

If a toxicant or drug is administered after binding sites on a protein are occupied by another chemical, competition for the site occurs, and a higher concentration of free drug may be available. Competition for the same site on plasma proteins may have especially important consequences when one of the potentially toxic ligands has a very high affinity. If compound A has low fractional binding (for example, 30%) and compound B displaces 10% of A from the protein, the net increase of free A is from 70% to 73%, a negligible increase. However, if A were 98% bound and 10% is displaced, the amount of free A increases from 2% to 12%, a sixfold increase in free toxicant. A change in binding may also occur when a second drug produces an allosteric effect resulting in altered affinity of the protein for the originally bound drug (noncompetitive binding). There is great debate as to the clinical significance of such drug–protein displacements that increase drug free fraction, since, as will be seen in the next section on mechanisms of free-drug elimination, the increased free concentration of drug may result in its increased elimination from the body, negating any enhanced activity or toxicity secondary to the displacement.

Most pharmacokinetic models in both human and comparative medical literature assess only total drug concentrations. When the extent of protein binding differs dramatically between species, inappropriate extrapolations often occur if the drug is very highly protein bound in one species. Similarly, interpretation of the extent of tissue distribution when the extent of protein binding is not known may be misleading. The most precise predictions can often be made when the free fraction of drug is known over the concentration ranges of the study being conducted.

Other Factors Affecting Distribution

Among the factors that affect distribution, apart from binding to blood macromolecules per se, are the route of administration, molecular weight, rate of metabolism, polarity, and stereochemistry of the parent compound or metabolic products, and rate of excretion. Molecular weight, charge, and/or polarity have been previously discussed. Stereoselectivity in the disposition of a drug is an often ignored phenomenon which could influence many studies. Its impact on metabolism is obvious; however, any receptor-mediated binding or transport process, including high-specificity protein binding could be affected. Propranolol and ibuprofen have been shown to demonstrate stereoselective distribution.

A major factor determining distribution is the extent of tissue binding, a process identical to that of serum protein binding except that the results on drug disposition are opposite. Tissue binding is governed by the same mechanisms as discussed above and tends to increase a drug's distribution, although not necessarily activity, if the drug is sequestered away from active drug receptors or target microorganisms. Covalent binding also occurs and is relevant to toxicology and tissue residue depletion. Depending on the pharmacokinetic model employed, irreversible covalent tissue binding may actually be mathematically detected as an increase in the drug's elimination, if only blood samples are used in the analysis, since there is no redistribution of drug back into the blood. For distribution to be quantitated, the basic assumption in most pharmacokinetic models is that the process is irreversible and thus ultimately an equilibrium will be achieved between drug movement into and out of tissue. When irreversible binding occurs, compound is extracted from blood and when excretory output (e.g., urine, feces, expired air) is not monitored, this is interpreted in many models as elimination. These model assumptions are often ignored.

As can be appreciated from this discussion, there are numerous factors that could affect distribution of a compound to tissues. Another is the methodology used to assess tissue distribution. Autoradiography is an excellent technique to anatomically localize distributed drug to the level of organs, cells, and even subcellular components. However, most pharmacokinetic studies rely on analytical techniques. When a tissue sample is collected from an animal, the sample is actually a homogenate of cells, extracellular fluid, and blood. The concentration measured cannot be uniquely assigned to any specific tissue or body fluid compartment. The use of microdialysis and ultrafiltration provides a direct estimate of extracellular fluid concentrations.

The extent of distribution of a compound is termed its volume of distribution (*Vd*) and is calculated by equations such as Equation 2.5:

$$\mathrm{Vd}(1) = \mathrm{Dose\ (mg)/Concentration\ (mg/l)} \qquad (2.5)$$

The *Vd* is actually a proportionality constant relating the plasma concentration to administered dose. Actual approaches to determine this will be presented in Chapter 3.

Renal Elimination

The ultimate route for drug elimination from the body is the kidney. Drugs can also be eliminated in bile, sweat, saliva, tears, milk, and expired air; however, for most therapeutic drugs these routes are generally not quantitatively important as mechanisms for reducing total body burden of drug. The degree of lipid solubility and extent of ionization in blood determines how much of drug will be excreted by the kidney. For drugs that are first biotransformed by the liver, the more water-soluble metabolites are then ultimately excreted through the kidney into the urine. The kidney has also been the most widely studied excretory organ because of the accessibility of urine to collection and analysis. Many of the principles utilized by pharmacologists in quantitating excretory organ function, especially clearance, were originally developed by renal physiologists to noninvasively assess kidney function. Dr. Homer Smith's classic reference on renal physiology is still instructive for the determination of renal clearance.

There are two components relevant to any discussion of renal drug excretion: physiology and quantitation. Renal drug excretion can be considered using the same principles of membrane transport developed earlier, except in this case the movement is from the vascular system to outside the body. Generally, only drugs that are either dissolved in the plasma or bound to circulating blood proteins are available for excretion. The pharmacokinetic parameter estimated by most of these approaches is the renal clearance of the drug.

Renal Physiology Relevant to Clearance of Drugs

For a perspective of drug excretion from the body, the kidney will be considered only as an excretory organ designed to remove foreign compounds (e.g., drugs) and metabolic by-products (e.g., creatinine, urea) from the blood. As will become evident, the major clinical indices of renal function such as blood urea nitrogen, serum creatinine, and creatinine clearance are actually pharmacokinetic parameters of creatinine and urea excretion!

The kidney receives approximately 25% of the cardiac output and thus processes a prodigious amount of blood. The kidney functions in a two-step manner to accomplish its function. The first step is passage through a filtering unit to retain formed cellular elements (e.g., erythrocytes, white blood cells) and proteins in the blood, only allowing the passage of plasma fluid into the remainder of the kidney. The second step utilizes a system of anatomically and physiologically segmented tubules to further modify the contents of the filtered fluid depending on a host of physiological needs including but not limited to fluid, electrolyte, and acid–base balance and the regulation of systemic blood pressure.

The primary functional unit of the kidney is the nephron depicted in Figure 2.8. Depending on the species, there may be 500,000 nephrons per kidney. The sum of their individual function is the observed organ function. Their specific anatomical arrangement is species dependent, often determined by the evolutionary adaptation of the animal to its environment relative to the need to conserve body fluids. The filtration unit is the glomerulus, while the remainder of the fluid processing is accomplished by the extensive tubular system, whose segments are named in relation to their relative distance

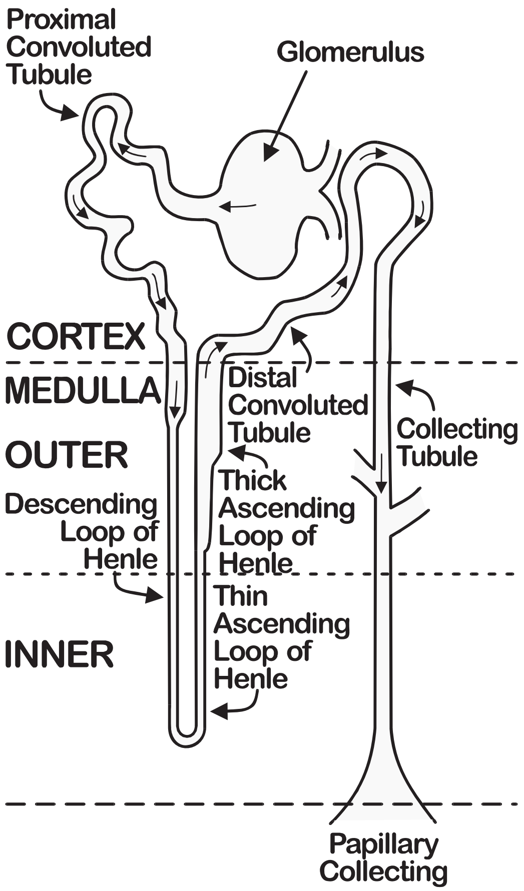

Figure 2.8 Structure of a nephron.

(proximal versus distal) measured *through* the tubules from the glomerulus. The junction between these is a unique anatomical adaptation called the loop of Henle that is designed to use countercurrent exchangers to efficiently produce a concentrated urine since most of the water that is filtered by the glomerulus must be reabsorbed back into the body. The loop of Henle also forces the distal tubules to return toward the surface of the kidney to interact with the glomeruli. Grossly, the region of the kidney containing the glomeruli as well as the proximal and returning distal tubules are on the outside toward the surface and comprise the renal cortex. This region of the kidney is very well perfused by blood and is primarily characterized by oxidative metabolic processes. The interior region is the medulla that is occupied by the penetrating loops of Henle, is poorly perfused, and is characterized by anaerobic metabolism. The amount of tubular fluid filtered by the glomeruli is acted upon by the various nephron segments to reabsorb wanted materials (primarily water and sodium) back into the blood and to let the remainder be excreted into the urine.

The kidney is also the site where acid–base balance is metabolically tuned by controlling acid and base excretion. Some of these processes are coupled to electrolyte secretion (e.g., potassium and sodium) and thus are further modulated by hormones such as aldosterone. These nephron functions may inadvertently alter the amount of drug eliminated in the tubules by changing tubular fluid pH and consequently the ionized fraction of weak acids and bases according to the Henderson–Hasselbach equation presented earlier. This modification in tubular fluid may affect the value of renal clearance determined in pharmacokinetic studies.

There are specific tubular transport systems that excrete products directly into the tubular fluid, which are not filterable because of plasma protein binding. Other transport systems reabsorb essential nutrients (e.g., glucose) back into the blood that were filtered into the tubular fluid. Drugs are also processed by these same transport systems making drug excretion dependent upon the physiological status of the animal. This is especially true when a drug biochemically resembles an endogenous substrate. As is similar to all transport processes, saturation and competition may occur, which may impart nonlinear behavior on a drug's kinetics.

Mechanisms of Renal Drug Excretion

Drugs are normally excreted by the kidney through the processes of (i) glomerular filtration, (ii) active tubular secretion and/or reabsorption, and/or (iii) passive, flow-dependent, nonionic back diffusion. These processes can be considered as vectorial quantities, each possessing magnitude and direction relative to transport between tubular fluid and blood. Their sum determines the ultimate elimination of a specific drug by the kidney as illustrated in Figure 2.9. *The total renal excretion of a drug equals its rate of filtration plus secretion minus reabsorption.* If a drug is reabsorbed back from the tubular fluid

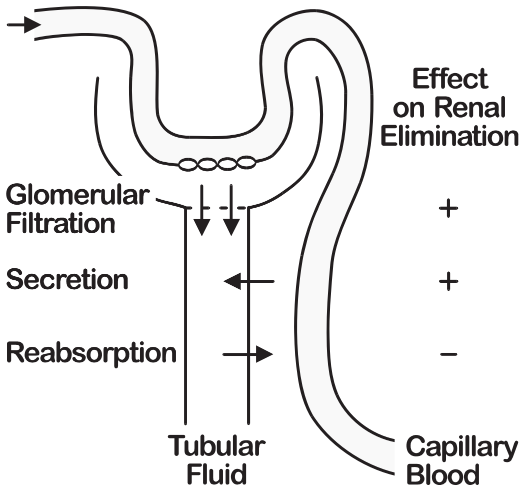

Figure 2.9 Vectorial processes of nephron function and their net effect on overall renal drug elimination.

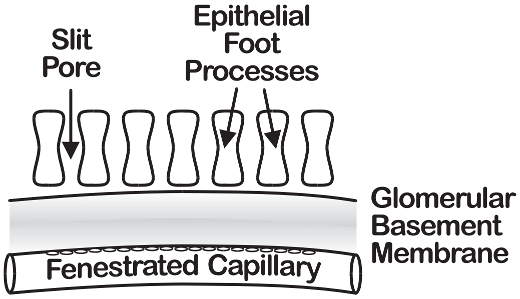

Figure 2.10 The glomerular filtration barrier.

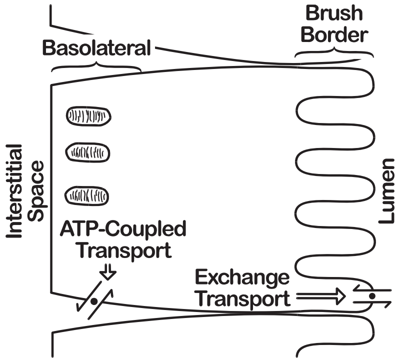

Figure 2.11 Schematic of a renal tubular cell illustrating location of active and exchange transport systems.

into the blood, its net renal excretion will be reduced. In contrast, if a drug is secreted from the blood into the tubular fluid, its net excretion will be increased. These events will be subsequently quantitated.

Excretion by glomerular filtration is unidirectional with drug removal from the blood by bulk flow. Only non-protein-bound drugs are eliminated by this process, a characteristic that is important when predicting elimination pathways for drugs. The rate of drug filtration, therefore, is dependent upon both the extent of drug protein binding and the glomerular filtration rate (GFR) whose calculation will be developed below.

Glomerular filtration is essentially ultrafiltration through the relatively permeable glomerular filtration barrier, which consists of the epithelial cells of Bowman's capsule, the glomerular basement membrane, and the slit-pores formed from juxtaposing epithelial foot processes (Figure 2.10). These possess a fixed negative charge that is a major contributor to the rate-limiting aspect of this barrier. When damaged, filtration selectivity is impaired and proteins may pass into tubular fluid. This is the primary manifestation of glomerular diseases that affect drug excretion.

The magnitude of active tubular secretion is not affected by the extent of plasma drug protein binding. These saturable, carrier-mediated processes are energy dependent and described by the laws of Michaelis–Menten enzyme kinetics. In order to promote absorption from the tubular filtrate into blood, tubule cells have microvilli, much like the intestinal mucosal cells, which maximize the surface area to cell volume ratio presented to the tubule. For secretion from the interstitial space into the tubule lumen, the basolateral surfaces of these cells (side facing the capillaries) have intensive membrane invaginations that also increase the surface area for interaction with the perfusing capillaries to facilitate active secretion. To provide the energy to drive these processes, proximal tubule cells have high mitochondrial densities to generate ATP, which fuels the Na^+-K^+ ATPase-coupled transport systems. This high level of oxidative metabolism is the primary reason for the sensitivity of the kidney to hypoxic or anoxic conditions, which result in renal damage if blood perfusion is interrupted even for short periods of time.

The cellular structure of transport systems across tubule cells involves two separate pairs of transport proteins, which creates an overall "polarity" of tubule cell function relative to the interstitial fluid and tubular lumen (Figure 2.11). One set is located in the brush border of the interface with tubular fluid and the other is located in the basolateral membrane. Energy coupling with ATP generally occurs in the basal portion of the cell (proximity to mitochondria), which, in secretion, builds up intracellular drug concentrations that are then transported to the tubular fluid by concentration-driven facilitated transport carriers. In reabsorption, the reverse occurs as the basolateral active "pumps" create low intracellular drug concentrations, which promote facilitated carrier-mediated reabsorption through the brush-border tubular membrane. Most transport systems are also stoichiometrically coupled to the transport of an electrolyte (e.g., Na^+, K^+, Cl^-, H^+), which assures electrical neutrality and provides a mechanism for modulating the systemic concentrations of these elements. The primary ion, which drives these transporters and which regulates overall renal function, is sodium. Thus, all drug transport systems are usually coupled to a Na^+ ATPase transmembrane system whose structure and polarity will determine the nature and direction of drug movement.

There are two distinct secretory pathways in the later sections of the proximal renal tubule that are relevant to a discussion of drug and toxicant excretion: one for acidic and one for basic compounds; the so-called organic anion and organic cation transporters. There are multiple types within each class and most do not show absolute substrate specificity. The primary orientation of this system is from blood to tubular filtrate, removing drugs and/or metabolite conjugates from the blood. Active reabsorption systems are also present that act on a drug already present in the filtered load. These systems are generally present to recover essential nutrients (e.g., glucose) that have been filtered by the glomerulus. Some drugs reach their target sites by this mechanism making their tubular fluid concentration more important for predicting activity than their blood concentrations. An excellent example is the diuretic furosemide that is first secreted by the tubules into the tubular fluid and then is actively reabsorbed back into the tubular cells to gain access to its receptors for activity. Thus, the best concentration–time profile to predict the diuretic action of furosemide is that of the urine rather than blood.

Drugs (and other endogenous substrates) may compete for tubular transport sites, thereby functioning as reversible, competitive inhibitors. This interaction has been classically studied with the organic acid transport system. Weak acids such as probenecid or phenylbutazone will inhibit secretion of the weak acid penicillin, thereby prolonging penicillin blood concentrations. Thus, when more than one drug in the same ionic class is administered, and they compete for the same organic ion transporter, their rate and extent of renal excretion will be affected. Many drug metabolites are conjugates (e.g., glucuronides) produced by Phase II hepatic biotransformation reactions and secreted by the transport system for weak acids, which may further complicate the pattern of drug excretion.

There are direct pharmacokinetic implications to the carrier-mediated mechanism of renal tubular drug secretion. The limited capacity of carrier-mediated processes means that above certain blood drug concentrations, transport will proceed at a maximal rate independent of concentration in blood; that is, so-called *nonlinear zero order kinetics* will become controlling, which will have adverse effects on the utility of normal linear pharmacokinetic models. These factors may become more important in renal disease states where renal capacity is already diminished. Under these circumstances, drug renal clearance will approach the glomerular filtration rate because additional drug concentrations in blood will not now be secreted into the urine. At subsaturation concentrations, renal clearance of an actively secreted substance is dependent on and limited by renal plasma flow and thus flow-limited mechanisms discussed below will become important considerations.

The final determinant of a drug's renal disposition is the mechanism of nonionic passive tubular reabsorption, or back diffusion, a process dependent upon urine flow rate, lipid solubility of the nonionized drug moiety, and urine pH. At low urine flow rates, there is greater opportunity for diffusion of drug from the distal tubular fluid back into the blood. Diffusion is facilitated by the high concentration of drug in the tubular fluid. Polar compounds having low lipid solubility, such as many drug metabolites, are not reabsorbed since they cannot cross the lipid membrane. In contrast, lipid-soluble, nonionized drugs are reabsorbed into the blood. The ratio of ionized to nonionized molecules determines the concentration gradient that drives the drug into the fluid. The extent of reabsorption is again a function of the drug's pKa and the pH of the tubular fluid, as described by the Henderson–Hasselbach equations (see Equations 2.2 and 2.3). The pH of the urine can undergo drastic changes as a function of diet and coadministered drugs (e.g., urine acidifiers and alkalizers). Tubular reabsorption of organic acids occurs with pKa values between 3.0 and 7.5 and for basic drugs with pKa values between 7.5 and 10.5. Weak acids thus are reabsorbed at low urinary pH (acidic), while weak bases are reabsorbed at high urinary pH (alkaline). Therefore, the renal excretion of an acidic drug decreases in acidic urine but increases in alkaline urine.

This principle is employed in treating salicylate intoxication in dogs. A brisk, alkaline diuresis is induced to decrease salicylate reabsorption into the blood and hasten excretion into the urine by trapping the salicylic acid in an ionized form in the alkaline urine. Reabsorption is further decreased by the elevated urinary flow rate. In contrast, induction of an alkaline diuresis will enhance the toxicity of basic drugs by increasing the amount of tubular reabsorption. Drugs often employed in critical care situations, such as procainamide or quinidine, have increased reabsorption and thus systemic activity in this alkaline state.

Species differences in urinary pH can have a major influence on the rate of renal excretion of ionizable drugs. Carnivores tend to have a more acidic (pH 5.5–7.0) urine than herbivores (pH 7.0–8.0). Thus, with all other disposition factors being equal, a weakly acidic drug will have a higher renal excretion in herbivores than in carnivores and a weakly basic drug will have a greater renal excretion in carnivores than in herbivores. In healthy animals, small changes in urinary pH or urine flow rate do not significantly contribute to altered drug clearance. However, with decreased function in renal disease, there is a decreased tubular load of drug. Altered urinary pH theoretically could further decrease overall drug clearance.

There are two other peculiarities of renal tubular transport that must be discussed before quantitating these processes. Some drugs are reabsorbed into the tubules by pinocytosis. This occurs by interaction of filtered drug in the tubular fluid with the brush border membrane. This is a very low-capacity and slow process that is easily saturated. Pinocytozed drugs are then transferred to lysosomes and generally digested in the cell (e.g., peptides and filtered proteins such as β_2 microglobulin). However, for some compounds, such as the aminoglycosides, enzymatic breakdown does not occur and the drug is essentially stored in the kidney. Therefore, although the drug is reabsorbed from the tubular fluid, it is not transported through the cell into the blood. Thus unlike other tubular reabsorption processes, reabsorption with storage or metabolism does decrease elimination of drug from the body. Such reabsorption has toxicological significance because the drug does accumulate in the tubular cells and could produce an adverse effect. Finally, this phenomenon has a major influence on the prediction of tissue residue profiles in the kidney resulting from drugs with prolonged elimination half-lives (e.g., aminoglycosides).

The final confounding influence on determination of renal drug clearance is when a drug is metabolized by the kidney. Most of the Phase I and Phase II enzymatic systems present in the liver also exist in the kidney, although different isozymes may be expressed. Oxidative processes generally occur within the proximal tubule cells. Two scenarios may occur. The first is when the drug is solely metabolized by the kidney and not the liver, or a combination of both processes occurs. The second is when *relay* metabolism occurs and the kidney further metabolizes a drug already biotransformed by the liver. These interactions are complex and generally are of toxicological significance.

Renal drug biotransformation may also occur in the medulla by anaerobic metabolic processes (e.g., prostaglandin endoperoxide synthetase). This process is small relative to reducing overall body burden because only 1% of renal blood flow delivers compounds to this region, but it has toxicological significance to the renal medulla where drug and/or metabolite may accumulate. Finally, brush border enzymes are present that metabolize peptides in the filtered tubular load to amino acids for reabsorption. Stereoselectivity in both active tubular secretion and metabolism in the kidney may occur with specific drugs (e.g., quinidine). The implications to assessment of renal drug excretion is similar to that of drugs metabolized by the kidney and is usually not taken into account.

The Concept of Clearance and its Calculation

Clearance is a concept widely used to measure the efficiency of drug elimination from an organ or the whole body. The concept was developed for use in assessing kidney function by renal physiologists. The problem with simply measuring the concentration of drug in urine as an index of its renal excretion is that the kidney also modulates the volume of urine produced in association with its primary mission of regulating fluid balance. Thus, the concentration of drug alone may be higher or lower depending on the ultimate urine volume. To accurately assess how much drug is eliminated, the product of volume of urine produced and the concentration of drug in urine (mass/volume) must be determined to provide the amount excreted (mass). If timed urine samples are collected, an excretion rate (mass/time) is determined. Similarly, to assess how efficient this process is, one must know how much drug is actually presented to the kidney for excretion. This is related to the concentration of drug in the arterial blood. The physiological concept of clearance was developed by early workers to generate a parameter that measured the true efficiency of renal excretion processes by assessing the total mass of compound ultimately excreted and relating it to the concentration of drug presented to the kidney for excretion.

There are two definitions of renal clearance that are used to define equations to calculate this parameter from real data. The first is *the volume of blood cleared of a substance by the kidney per unit of time*, that is, the volume of blood required to contain the quantity of drug removed by the kidney during a specific time interval. This will be derived when we have developed pharmacokinetic parameters in Chapter 3 to quantitate Vd and fractional excretion rates. The second definition is *the rate of drug excretion relative to its plasma concentration*. In both cases, the actual value for a drug's renal clearance is the vectorial sum of {filtration + tubular secretion − tubular reabsorption}, making it a parameter that estimates the entire contribution of the kidney to drug elimination. Similarly, any change in renal drug processing will be reflected in renal clearance *if* it is not compensated for by more distal components of the renal tubules.

There are two types of data needed to calculate clearance: (i) an estimate of blood drug concentration presented to the kidney and (ii) the amount of drug removed by the kidney. The latter can be estimated either by measuring the amount of drug excreted by the urine or comparing the difference between the renal arterial and venous drug concentrations to assess how much drug was extracted while passing through the organ.

To begin, we will use the classic approach (Equation 2.6), which directly measures extraction, based on Fick's Law:

$$\mathrm{Cl\ (ml/min) = (Q)\ (E) = (Q)\ \frac{\left(C_{art} - C_{ven}\right)}{\left(C_{art}\right)}} \tag{2.6}$$

where Q is renal arterial blood flow (ml/min), E is the extraction ratio and C_{art} and C_{ven} are arterial and venous blood concentrations. The obvious difficulty with this approach is that arterial and venous blood samples must be collected. However, renal physiologists realized that this approach could be modified to more easily assess renal function if a few assumptions were made.

The first is that the amount of substance removed or extracted by the kidney is equivalent to that which is excreted into the urine. If one makes a timed collection of urine and measures the urine concentration and volume, the amount (X) of drug extracted by the kidney over a specific time interval, that is, its *rate* of renal excretion denoted $\Delta X/\Delta t$, is the following (Equation 2.7):

$$\mathrm{\Delta X/\Delta t\,(mg/min) = \left[U_X\,(mg/ml)\right]\,[V\,(ml/min)]} \tag{2.7}$$

where U_x is the concentration of drug in urine and V is the urine production. Now the only component needed is the concentration presented to the kidney. Workers used constant rate intravenous infusion of chemicals to insure that so-called *steady state* blood concentrations were achieved. With this experimental design, the renal clearance of substance X is calculated as the following (Equation 2.8):

$$\mathrm{Cl}_{(\mathrm{renal})}\ (\mathrm{ml/min}) = (\Delta X/\Delta t)/C_{\mathrm{art}} = \mathbf{U_X}V/C_{\mathrm{art}} \quad (2.8)$$

This expression is equivalent to the definition for clearance above that relates the rate of drug excretion to its plasma concentration. This expression serves as the basis for many of the pharmacokinetic techniques to be developed in subsequent chapters.

Some minor discrepancies may result when drug clearances are calculated by use of blood or plasma data alone versus techniques such as those that employ urine collection. As discussed earlier, tubular reabsorption with storage (e.g., aminoglycoside antibiotics) will result in a lower $\mathrm{Cl}_{(\mathrm{renal})}$ calculated from urine data rather than blood-based methods because tubular reabsorption would not be reflected in the venous blood concentrations since the substance is now trapped in the tubular cells. A similar discrepancy may occur with intrarenal drug metabolism since this process does not return parent drug to venous blood. In a research setting, the difference is often used as conclusive evidence that either of these two phenomena actually occur.

Nonlinearity of Tubular Secretion and Reabsorption

The discussion thus far has been limited to determining clearances of substances that are primarily eliminated through glomerular filtration. The pharmacokinetics of this process are linear since saturation does not occur and only non-protein-bound drugs are filtered through the glomerular basement membrane complex. When the renal clearance of a drug eliminated by glomerular filtration is estimated, only the filtration of the free or unbound drug is assessed; thus changes in protein binding will change the net excretion of the drug. Drugs and toxicants that undergo passive tubular reabsorption obey Fick's Law of Diffusion since concentration gradients described again by linear first-order rate constants provide the driving force across the tubular epithelium. In contrast, compounds that are actively secreted from postglomerular capillaries across the renal tubules and into the tubular fluid show saturation at high concentrations, competition with drugs secreted by the same pathways, and dependence on the magnitude of renal blood flow; all hallmarks of nonlinear pharmacokinetic behavior. For such compounds, clearance will not be constant but rather will be dependent upon the concentration of drug presented to the kidney.

As tubular secretory pathways become saturated, a drug's clearance will decrease. To develop this concept, we will revisit our definition of a drug cleared by GFR and acknowledge that only the free or unbound drug concentration (C_f) is eliminated by filtration. Protein bound drug (C_b) cannot be filtered. Therefore, the rate of renal excretion ($\Delta X/\Delta t$) can be expressed as simply this (Equation 2.9):

$$\Delta X/\Delta t = C_f \times \mathrm{GFR} \quad (2.9)$$

As C_f becomes greater, $\Delta X/\Delta t$ will increase in direct proportion (e.g., linearly increase). However recalling Equation 2.8, its clearance will be $\Delta X/\Delta t$ *divided* by C_{art}. In this case, C_{art} is the total blood concentration presented to the kidney ($C_f + C_b$). Clearance thus equals the following (Equation 2.10):

$$\mathrm{Cl}_{(\mathrm{renal})} = (\Delta X/\Delta t)/C_{\mathrm{art}} \quad (2.10)$$

These relations have two implications. The first is that as total blood concentrations of drug increase, so does $\Delta X/\Delta t$; however, $\mathrm{Cl}_{(\mathrm{renal})}$ remains constant (Equation 2.11) because

$$\mathrm{Cl}_{(\mathrm{renal})} = (C_f \times \mathrm{GFR})/(C_{\mathrm{art}}) \quad (2.11)$$

and C_{art} will increase in direct proportion to $C_f + C_b$ as long as the fraction bound does not change. However, if the extent of protein binding of a drug is increased ($C_f \downarrow$, $C_b \uparrow$), its rate of renal excretion, $\Delta X/\Delta t$, will decrease as will its clearance since the C_{art} ($C_f + C_b$) will be constant. Therefore, drugs cleared by filtration have constant clearance with changing total drug concentrations but are sensitive to the extent of protein binding. This is one reason mentioned above in the discussion of plasma protein binding, that displacement of a protein bound drug that increases C_f will result in increased renal clearance, which then reduces its concentration to normal. For such a drug with high protein binding, only the small fraction presented for filtration can ever be extracted and cleared by the kidney. Since the total renal clearance of a compound is the sum of filtration plus secretion, a drug *solely cleared by filtration* will have a relatively low clearance compared to one that is also actively secreted. If one considers this in terms of the extraction ratio (E) defined above, Cl_B will always be less than the renal blood flow (Q) since the extraction ratio is less than one and dependent on the glomerular filtration fraction. Such drugs are termed *low extraction* drugs and their $\mathrm{Cl}_{(\mathrm{renal})}$ will be sensitive to the extent of protein binding. Examples of such drugs include inulin, the aminoglycoside antibiotics, tetracyclines, digoxin, and furosemide.

In contrast, consider a drug that also undergoes active tubular secretion. In this case, even a drug that is protein bound (C_b) or distributed into red blood cells will be secreted into the urine since the affinity for specific tubular transport proteins will be greater than that for the relatively nonspecific protein-binding sites or partitioning in erythrocytes. The extraction ratio will thus approach 1.0 and $Cl_{(renal)}$ will approach the renal blood flow Q. Such drugs are termed *high extraction* or *perfusion limited* to acknowledge the relationship of clearance to blood flow. The classic example is para-amino hippurate (PAH) because it is almost completely extracted as it passes through the kidney, making its clearance almost equal to renal plasma flow. In fact, PAH renal clearance had once been used in clinical situations to estimate renal blood flow. Other such drugs include many of the β-lactam antibiotics (e.g., penicillin) and many sulfate and glucuronide conjugate products of hepatic drug biotransformation. Another implication of active tubular secretion is that at sufficiently high concentrations, saturation of the secretory pathways may occur. Finally, the maximal renal clearance possible is renal blood flow.

The final pathway modulating renal excretion is when a drug undergoes passive tubular reabsorption. The dependency of this process on urinary pH has already been discussed. In this case, C_{art} will be constant but $\Delta X/\Delta t$ and thus $Cl_{(renal)}$ will vary depending on the urinary pH. Since this is an equilibrium process, time is required for this diffusion to occur. Thus if the renal clearance of a drug is dependent on urine flow, it is presumed to undergo passive tubular reabsorption. When high tubular loads are presented, reabsorption is overloaded as equilibrium cannot be achieved and nonreabsorbed drug is eliminated into the urine.

We have focused this discussion on renal drug elimination. However, clearance is used throughout physiology and pharmacokinetics to quantitate drug elimination through any organ as well as from the body. The relevant equation (Equation 2.12) defining the whole body clearance (Cl_B) of a drug is the sum of all elimination clearances:

$$Cl_B = Cl_{(renal)} + Cl_{(hepatic)} + Cl_{(other)} \tag{2.12}$$

Calculation of Cl_B provides an efficient strategy for estimating how a drug or toxicant is eliminated from the body as it indirectly compares systemic clearance to renal and hepatic clearances.

Hepatic Biotransformation and Biliary Excretion

Hepatic disposition is one of the final keys in the ADME scheme needed to describe the disposition of many drugs and chemicals in the body. The liver is responsible for both biotransformation and biliary excretion. In many ways, the liver should be considered as two separate organs, one encompassing metabolism and the other biliary excretion.

Drug localization and biotransformation in the liver are dependent on many factors associated with both the biological system and drug itself. These factors include the biological properties of the liver (chemical composition, relative activity of major drug metabolism enzymes, hepatic volume/perfusion rate, and drug accessibility to and extraction by hepatic metabolic sites) as well as the physicochemical properties of the drug (pKa, lipid solubility, molecular weight). In a quantitative sense, the liver is the major drug metabolism organ in the body.

Species differences in drug metabolic fate are, in most cases, the primary source of variation in drug disposition and, therefore, in drug activity or toxicity, across species. It has been estimated that 90% of drugs administered to humans are metabolized and polymorphisms in human metabolizing enzymes are responsible for the vast majority of adverse drug events. Extrapolation of metabolism data between animal species is an important issue as is the ability to correlate in vivo pharmacokinetic and metabolic data with in vitro metabolic findings.

Recalling our earlier discussion about the phenomenological role of metabolism in drug distribution and excretion, it would be hard to imagine what would happen in biological systems without xenobiotic metabolism. Absorbed compounds would stay in the body for a much longer period of time and have prolonged activity, tissue accumulation, and, potentially, toxicity. Metabolism is necessary for the animal or human body to rid itself of lipophilic xenobiotics as an effective defense mechanism against adverse effects. In general, the intensity of drug action is proportional to the concentration of the drug and/or its active metabolite(s) at the target site. On the other hand, drug-associated toxicity is also dependent on the chemical form (active or inactive) and concentration at the same or other relevant target site. Therefore, any process or factor that modifies the drug/metabolite concentration at a target site will cause an altered activity or toxicity profile. Drug metabolism may often result in metabolite(s) with altered chemical structures, which change the receptor type affected, drug–receptor affinity, or pharmacological effect. Most parent drugs can be deactivated to inactive metabolites. In contrast, some drugs can also be activated either from an inactive form (prodrug) to an active drug, or from an active form (e.g., meperidine) to an active metabolite (normeperidine) with similar activity/toxicity. Therefore, drug metabolism can either reduce or enhance parent drug's effect, create another activity, or even elicit toxicity, depending on both the drug and the biological system in question.

Therefore, the pharmacological and pharmacokinetic properties of a drug can be changed by metabolism in one or several of the following ways: pharmacological

Table 2.2 Drug metabolism reactions

Phase I	Phase II
Oxidation	Glucuronidation/glucosidation
Cyt P-450 dependent	Sulfation
Others	Methylation
Reduction	Acetylation
Hydrolysis	Amino acid conjugation
Hydration	Glutathione conjugation
Dethioacetylation	Fatty acid conjugation
Isomerization	

activation or deactivation; change in disposition kinetics of drug uptake (absorption from application site), distribution, and excretion (e.g., bile excretion, enterohepatic circulation, and renal excretion). The remainder of this chapter focuses on hepatic metabolism and drug hepatobiliary excretion in animal species and introduces some basic biochemical and pharmacokinetic concepts relevant to this role. Although these discussions are focused on the liver, the principles elucidated may also be applicable to extrahepatic sites of drug biotransformation.

Phase I and Phase II Reactions

Various metabolic pathways are involved in drug metabolism including oxidation, reduction, hydrolysis, hydration, and conjunction. These processes can be divided into Phase I and Phase II reactions (Table 2.2). Phase I includes reactions introducing functional groups to drug molecules necessary for the Phase II reactions, which primarily involve conjugation. In other words, Phase I products act as substrates for Phase II processes, resulting in conjugation with endogenous compounds, which further increase their water solubility and polarity, thus retarding tissue distribution and facilitating drug excretion from the body. Specific examples of drug metabolism are included in chapters throughout this text. The focus of this introduction will be to briefly overview the general processes involved in drug metabolism relative to how they might affect pharmacokinetic parameters and the disposition of drugs in the body. Interested readers should consult standard texts in drug metabolism or biochemical pharmacology/toxicology for specific detailed examples illustrating the chemistry and genetic control of these processes.

Our knowledge regarding the molecular mechanisms of drug metabolism has been predominately gained from studies on the liver at different experimental levels including in vivo intact animals; ex vivo liver perfusion; and in vitro liver slices, hepatocyte cell cultures, isolated/purified subcellular hepatocyte organelles, and isolated enzyme or enzyme components. Two subcellular organelles are quantitatively the most important; the endoplasmic reticulum (ER) (isolated in the microsome fraction) and the cytosol (isolated in the soluble cell fraction). Phase I oxidation enzymes are almost exclusively localized in the ER, along with the Phase II enzyme of glucuronyl transferase. In contrast, other Phase II enzymes are mainly present in the cytoplasm. Microsomal fractions of the hepatocyte retains most, if not all, of the enzymatic activity in drug metabolism.

Phase I metabolism includes four major pathways: oxidation, reduction, hydrolysis, and hydration, among which oxidation is the most important. Attention is usually focused on oxidation mediated by the microsomal mixed-function oxidase system (e.g., cytochrome P450, etc.) due to its central role and significance in governing the metabolic disposition of many drugs and xenobiotics. An understanding of this pathway is often critical to making interspecies extrapolations.

Phase II conjugating enzymes play a very important role in the deactivation of the Phase I metabolites of many drugs as well as in direct deactivation of some parent compounds when their specific structure doesn't require Phase I modification. For example, the analgesic drug paracetamol can be deactivated directly by Phase II reactions using glutathione, glucuronide, and sulfate conjugation mechanisms. Phase II deactivation can be achieved by both gross chemical modification of the drug thereby decreasing their receptor affinity, and by enhancement of excretion from the body, often via the kidney.

Among the reactions catalyzed by drug metabolism enzymes in the hepatic ER, cytochrome (Cyt) P450-dependent mixed-function oxidation is the most intensively studied. This reaction catalyzes the hydroxylation of hundreds of structurally diverse drugs and compounds, whose only common feature appears to be a relatively high lipophilicity. The enzyme consists of a family of closely related isoenzymes embedded in the ER membrane. Its name is based on the fact that the cytochrome is a pigment that exhibits a maximal absorbance wavelength of 450 nm when reduced and complexed with carbon monoxide. With the advent of gene cloning and sequencing, and the application of molecular biology techniques to Cyt P450 structure analysis, tremendous progress was made in the last decade in the isolation and sequencing of the cDNAs encoding multiple forms of the hemoprotein. The rapid determination of full-length Cyt P450 amino acid sequences enabled the development of a coherent nomenclature system describing hundreds of different and unique Cyt P450s.

A great deal of work has been fostered in this area through development of a nomenclature system for cytochrome P450 enzymes (CYP) based on DNA/amino acid sequence. This allows enzymes to be unambiguously classified. An enzyme is coded by its family (1,2,…) followed by subfamily (A–D) and then gene (1,2,…), and if necessary, allelic variant (*1, *2,…). Thus, a common

Table 2.3 Example of cytochrome P450 enzymes and substrates in the dog

Subfamily	Gene code	Sample substrates
1A	1A1, 1A2	Theophylline, phenacetin, 7-ethoxyresorufin, caffeine
2B	2B11	Ketamine, propofol, pentobarbital, warfarin
2C	2C21, 2C41	Diclofenic, midazolam
2D	2D15	β blockers, celecoxib, dextromethorphan
3A	3A12, 3A26	Macrolides, steroids, cyclosporine

enzyme found in dogs is termed CYP3A12, which is responsible for steroid oxidation. These enzymes are classified on the basis of sequence and not function. There is thus a great deal of overlap between substrate specificities and enzymes with different CYP identifications. The numbers are also species specific, thus preventing direct comparison between species. Not surprisingly, most work has been done for human enzymes, although recently work has also begun to define the primary enzymes involved in veterinary species. Table 2.3 lists some of the cytochrome P450 enzymes identified in the dog. This area of cytochrome P450 pharmacogenomics in the dog has recently been reviewed (Martinez et al., 2013).

Impact of Metabolism

One can precisely predict the impact of drug metabolism on therapeutic drug effect if one can identify the precise enzymes by which a drug is metabolized. The same enzymes are not involved in metabolizing the same drugs in different species and, in many cases, substrate specificities overlap, making precise prediction difficult. A variety of Phase I and Phase II reactions can take place simultaneously or sequentially in the body. For example, parathion can be catalyzed by Cyt P450 to an intermediate, which in turn can either be further oxidized to paraoxon or hydrolyzed to *p*-nitrophenol followed by conjugation reactions. Finally, as discussed earlier, a compound metabolized in the liver may be subsequently metabolized in the kidney prior to excretion, making it possible for these various metabolic steps to be carried out in multiple organs. Stereochemistry also plays a major role in drug metabolism since most enzyme system can be stereoselective. Examples include the enantiomers of amphetamine, cyclophosphamide, pentobarbitone, phenytoin, verapamil, and warfarin. Large differences in enzyme expression and function occur between species. Many of these were first identified in broad differences in the ability of some species studied to perform Phase II reactions (e.g., cats deficient in glucuronidation, pigs in sulfation). We now know that this is even more complex, especially in species and breed differences in specific CYP isoenzymes.

To further complicate this scenario, there is often overlap between cytochrome P450 substrate specificities and those for P-glycoprotein. That is, the same drug may be handled by both systems, classic examples being cyclosporine and ketoconazole. Such phenomena are often detected by complex and species-specific drug–drug interactions. For compounds handled in such a fashion, one can be assured that large differences will be seen between animal species making interspecies extrapolations very difficult.

In summary, Phase I metabolism is primarily responsible for drug deactivation, although Phase II plays an important role in deactivation of some drugs. Phase I reactions prepare drugs or toxicants for Phase II metabolism; that is Phase I modifies the drug molecule by introducing a chemically reactive group on which the Phase II reactions can be carried out for the final deactivation and excretion. This increased water solubility after metabolism restricts a drug's metabolite distribution to extracellular fluids, thereby enhancing excretion. Specific pathways for drug metabolism and transport are discussed in the individual drug chapters as well as their pharmacogenomics in Chapter 50.

Hepatic Clearance

As presented in our discussion on renal excretion, clearance of a drug by an organ ($\mathrm{Cl_{org}}$) can be ultimately defined as a function of its blood flow ($\mathrm{Q_{org}}$) and its extraction ratio ($\mathrm{E_{org}}$) expressed in Equation 2.6 as $\mathrm{Cl_{org} = Q_{org}\,E_{org}}$. The ability of the liver to remove drug from the blood, defined as *hepatic clearance*, is related to two variables: intrinsic hepatic clearance ($\mathrm{Cl_{int}}$) and rate of hepatic blood flow ($\mathrm{Q_h}$), as defined in Equation 2.13:

$$\mathrm{Cl_h = Q_h\left[Cl_{int}/\left(Q_h + Cl_{int}\right)\right] = Q_h E_h} \tag{2.13}$$

where Cl_h is the hepatic clearance, Q_h is the hepatic blood flow, and $Cl_{int}/(Q_h+Cl_{int})$ is the hepatic extraction ratio or E_h. Intrinsic clearance ($\mathrm{Cl_{int}}$) is conceptualized as the maximal ability of the liver to extract/metabolize drug when hepatic blood flow is not limiting. It represents the inherent metabolic function of all enzyme systems in the liver to metabolize the drug in question. As seen in Equation 2.13, when $\mathrm{Cl_{int} \gg Q_h}$, hepatic extraction ratio ≈1.0 (*flow limited or high extraction*, usually seen with $\mathrm{E_h > 0.8}$), $\mathrm{Cl_h}$ is dependent only on the blood perfusion rate $\mathrm{Q_h}$. The more blood passing through the liver, the more drug molecules will be extracted by the liver for metabolic elimination. A hepatic blood perfusion-dependent hepatic clearance will then be seen. Drugs with such high extraction ratios will show significant first-pass metabolism after oral administration to the

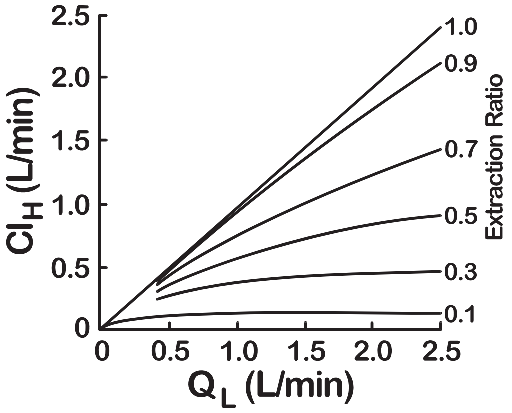

Figure 2.12 Relationship between liver blood flow (Q) and hepatic clearance (Cl_H) for drugs with different hepatic extraction ratios. Extraction ratio values are at a blood flow of 1.5 l/min.

extent that this route of administration may not produce effective systemic drug concentrations. Finally, the highest hepatic Cl possible is Q_h.

In contrast, if $Cl_{int} \ll Q_h$, the E_h is close to zero and thus the Cl_h is dependent only on the Cl_{int}; that is the liver extracts as many drug molecules as it can from the blood flow presented (*metabolism limited or low extraction*, usually with E_h <0.2). These two extremes occur with propranolol and antipyrine, respectively. Intermediate values of extraction ratio of 0.2–0.8 give hepatic clearance rates that can be dependent to varying extents on both hepatic blood perfusion rate and intrinsic clearance. Based on earlier discussions, one can appreciate that such classifications are very species specific since they depend upon the presence of specific enzyme systems for the specific drug.

To estimate hepatic drug clearance, one must consider the drug's physicochemical properties, hepatic drug metabolism enzyme activity, and rate of hepatic blood perfusion. This relationship between hepatic clearance and liver blood perfusion rate for drugs with different extraction ratios can be appreciated when Equation 2.13 is plotted in Figure 2.12. With a lower hepatic extraction drug, the blood perfusion rate is less important to $Cl_{hepatic}$. For a high hepatic extraction drug, the $Cl_{hepatic}$ is proportional to the blood flow, as discussed earlier. The reader should note the similarity of this discussion to that introduced earlier concerning capacity or flow-limited renal tubular clearance. The concepts are identical for both organs; however, they are more often employed when hepatic clearance is modeled due to the much greater difference in species-inherent metabolic capacities.

Metabolism Induction and Inhibition

Drug metabolism is substantially influenced by enzyme induction or inhibition that occurs secondary to the deliberate or passive intake of a number of chemicals that animals are increasingly exposed to either in the environment, for medical reasons, as dietary supplements, or in humans simply as a result of lifestyle (smoking, alcohol consumption, etc.). In laboratory animals, contaminants and natural constituents of diet have been shown to affect the pattern of drug metabolism observed. In many cases, the compound itself may alter its own metabolic fate by induction or inhibition.

Induction

Many currently used drugs, food additives, household chemicals, and environmental contaminants (including pesticides) possessing diverse chemical structure, pharmacological or toxicological activity are well known to induce their own metabolism and/or that of other compounds in humans and animals. Induction of metabolism may arise as a consequence of increased synthesis (at different transcriptional/translational levels), decreased degradation, activation of preexisting components, or a combination of these processes. With so many compounds able to alter hepatic metabolism, a great deal of effort has been spent in recent years to understand the mechanisms behind these processes. This is important from a therapeutic perspective since the intrinsic hepatic clearance of a drug will change if the enzymes responsible for metabolizing it are induced, thereby increasing metabolic capacity. Similarly, the pattern of Phase I and Phase II metabolism may be changed if one enzyme component's activity has been modified by inducers. These interactions introduce a significant complexity to pharmacokinetic models describing the disposition of drugs extensively metabolized by the liver. However, they have also prompted research efforts aimed at elucidating the mechanisms behind these processes, which, when understood, should provide a strategy for developing mechanistically meaningful models for simulation of drug metabolic disposition.

As discussed above, the activity of the Cyt P450 system is of particular importance to the overall hepatic metabolic clearance of a drug. In the mid-1960s, both Cyt P450 and its associated flavoprotein reductase were found to be induced by phenobarbitone pretreatment that was accompanied by induction of drug metabolism. Induction was generally accompanied by increases in liver microsomal Cyt P450 content. Diverse drug metabolism responses to different inducers, which all induce hepatic Cyt P450, can be dependent on the substrate of interest (substrate specificity) with stero- and regioselectivity, confirming that subpopulations of Cyt P450 (isoenzymes) might be present. This now widely accepted concept has had a profound influence on drug discovery, design of metabolism studies, and the resulting structure of pharmacokinetic models. With the advent of the CYP nomenclature system discussed above, enzymes can now be classified both as to substrate specificity, but also as to which compounds induce or inhibit their function. Pharmacogenomic studies have begun to identify the specific genes responsible for isoenzyme induction and also identify species differences. Unfortunately, these studies are just beginning to be applied in veterinary species and a complete picture is still lacking on their impact on clinical therapeutics. A major cause of this problem is that, as mentioned above, there are not specific homologs between human and veterinary species enzymes, making marker substrates different. The important concept is that induction will occur and could have a significant impact on therapeutic efficacy. Specific examples of such interactions are presented within the drug-specific chapters of this text.

Metabolism Inhibition

Similar to the induction of metabolism, inhibition is a well-recognized phenomenon secondary to serial drug dosing, coadministration of drugs, endogenous compounds, environmental xenobiotics, and complex multiple-ingredient drug formulations. Several mechanisms for metabolism inhibition have been noted, including the destruction of preexisting enzymes (by porphyrinogic drugs and xenobiotics containing olefinic ($C = C$) and acetylenic ($C \equiv C$) functions), inhibition of enzyme synthesis (by metal ions), or complexing with the hemoprotein thereby inactivating enzymes. Many drug–drug interactions may be explained at the level of Cyt P450 destruction. In contrast to the porphyrinogic drugs, metal ions such as cobalt exert their inhibitory effects by modulating both the synthesis and degradation of the heme prosthetic group of Cyt P450. Formation of inactive Cyt P450-inhibitor complex is another mechanism for drug metabolism inhibition. Inhibitors are usually substrates of Cyt P450 and require metabolic conversion to exert their full inhibitory effects, in a manner similar to porphyrinogic drugs and xenobiotics. However, inhibitors forming complexes with hemoprotein are metabolized by Cyt P450. These inhibitors can form metabolic intermediates or products that tightly bind to the hemoprotein, thereby preventing its further participation in drug metabolism. As can occur with induction, coadministration of inhibitor drugs may result in clinically important drug interactions. Specific examples of such interactions are presented within the drug-specific chapters of this text.

Biliary Drug Elimination

As an exocrine function of the liver, bile excretion is thought to be present in almost all vertebrates. The three basic physiological functions of the bile are (i) to serve as the excretory route for products of biotransformation, (ii) to facilitate the intestinal absorption of ingested lipids such as fatty acids, cholesterol, lecithin, and/or monoglycerides due to the surfactant properties of bile forming mixed micelles, and (iii) to serve as a major route for cholesterol elimination in order to maintain normal plasma cholesterol levels. In addition to its physiological functions, bile is also pharmacologically and toxicologically important since some heavy metals and enzymes are also excreted via the biliary system. Bile secretion is very important to chemical/drug transport and elimination under both physiological and pathological conditions. However, bile secretion has proven difficult to study mainly due to the inaccessibility of the biliary tree for direct sampling.

The Mechanism of Bile Formation

Bile is continuously produced by liver cells and then stored in the gall bladder, except for those species (rat, horse) lacking it. The pH of bile ranges from 5.0 to 7.5 depending mainly on the animal species. Biliary excretion is a major route for some drugs with MW >300 and a high degree of polarity. This occurs by active transport of drug and metabolites into bile, thus saturation and competition are important issues to consider. Passive diffusion of drug into bile is insignificant. Most of the compounds secreted into bile are finally excreted from the body in feces where they may be subject to enterohepatic circulation and degradation by intestinal microflora.

Bile is formed at two sites: the ramifications of the bile duct within the portal triads and the anastomosing network of the narrow bile canaliculi in the hepatic parenchyma. The bile canaliculi are the primary secretory units of the liver. These small channels or furrows are lined by the apical membranes of the hepatocytes and thus do not have their own epithelium or basement membrane. Because hepatocytes form a canalicular lumen wherever they abut, most canaliculi communicate with each other, forming an anastomosing network. Similar to the relationship of the nephron to the kidney, the volume and composition of canalicular bile are often determined by the activity of several cords of hepatocytes.

The overall bile flow is in the opposite direction to sinusoidal blood flow and thus solute transfer from plasma to bile involves a counterflow process (Figure 2.13). Such a blood–bile flow pattern reduces rediffusion of biliary solutes such as drugs and metabolites back into sinusoidal plasma in the portal area, which is richer in solute concentration, bathes periportal hepatocytes, and is exposed to higher canalicular concentration of any given solute. Three routes of fluid and drug transfer from the sinusoid to the bile canaliculus have been postulated: transcellular, paracellular, and vesicular. These multiple mechanisms contribute to the large interspecies differences seen in biliary drug excretion.

Drug uptake into hepatocytes by passive diffusion is so efficient that it is rate limited by the delivery of the

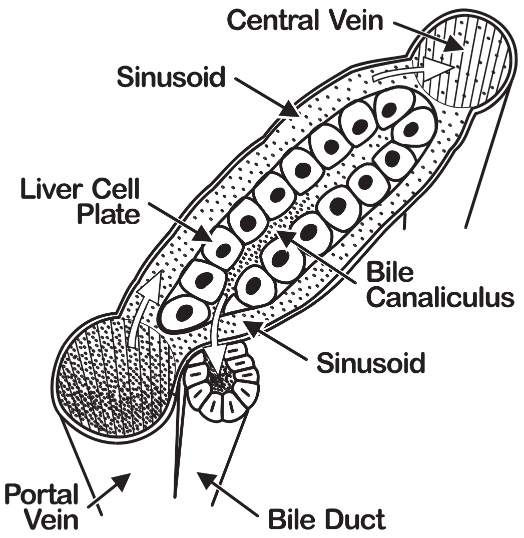

Figure 2.13 Gradient concept of bile secretion in a liver lobule.

drug to the liver (i.e., blood flow) rather than membrane transport, thereby exhibiting flow-dependent clearance. However, for highly polar molecules, passive diffusion is not an efficient mode of hepatocellular uptake, and there is an increased reliance on carrier-mediated transport systems. Drug metabolites, particularly conjugated metabolites (e.g., sulphates and glucuronides), are invariably more polar than their precursors and thus are more likely to experience hepatocyte membranes as diffusional barriers. With such a barrier, the hepatocellular export of a locally formed metabolite will depend on the presence and activity of carrier-mediated transport systems for sinusoidal efflux and biliary excretion. Transport systems of current interest include the P-glycoproteins, which are responsible for the biliary excretion of a range of organic cations, and the canalicular multispecific organic anion transporter. Intracellular trapping of metabolites formed in the liver, secondary to low membrane permeability, is clinically important because many are potentially hepatotoxic and/or capable of interfering with the hepatic transport of endogenous compounds or other drugs and metabolites. Again this phenomenon is conceptually similar to renal tubular sequestration and has similar pharmacokinetic implications. Finally, if the metabolite is unstable, intracellular accumulation can lead to the regeneration of the precursor and so-called “futile cycling” within hepatocytes.

Biliary Drug Transport

Some parent drugs and numerous drug metabolites derived from hepatic metabolism are excreted in the bile into the intestinal tract. The excreted metabolites can be excreted via feces although, more commonly, they are subject to reabsorption into the blood and are eventually excreted from the body via urine. There are at least three different biliary transport pathways for organic anions, cations, and neutral compounds, although metals may also have their own transport carriers/systems. Both *organic anions* and *organic cations* can be actively transported into bile by carrier systems again similar to those involved in the renal tubule. Such transport systems are nonselective, and ions with similar electrical charge may compete for the same transport mechanisms. Additionally, a third carrier system, whose activity is sex dependent, may be involved in the active transport of *steroids* and *related compounds* into bile. In contrast to renal excretion, amphiphatic drugs (those having both polar and nonpolar properties) are preferentially excreted in the bile. The drug (or metabolite) excreted into the small intestine can be reabsorbed into blood forming the so-called drug enterohepatic cycle. This is an important factor changing the blood : liver or liver : bile drug concentration ratios during studies of the hepatobiliary transport mechanisms and drug hepatic elimination.

The biliary excretion of weak acids is the most important mechanism in drug hepatic elimination. Bromosulfophtalein (BSP) and analogues are dyes used as diagnostic probes of liver function and model substances in studies of the hepatic uptake of organic anions. Antibiotics such as ciprofloxacin can be actively excreted into bile in the presence of a biliary tract obstruction. Tetracyclines, mainly excreted into urine via glomerular filtration, are also concentrated in the liver and accordingly excreted into the small intestine via the bile, and then partially reabsorbed.

Glucuronides of endogenous compounds and drugs can be actively transported from hepatocytes into bile via transport systems similar to those for organic anions. Glucuronide conjugates are very important in hepatic drug metabolism and biliary excretion. The effectiveness of biliary excretion for glucuronide conjugates can be greatly limited by enzymatic hydrolysis after the bile is mixed with the small intestine contents, thereby releasing the parent drugs to be reabsorbed and enter the enterohepatic cycle. The reabsorbed drugs and metabolites can be ultimately excreted in urine. Some drug metabolites further undergo either biotransformation in the liver or other organs or are subjected to microbiological and physicochemical degradation in the small intestine before being excreted in the feces.

Weak bases can be actively transported into bile via carrier systems similar to the renal transport processes. Atropine, isoproterenol, and curare are eliminated by this mechanism, with atropine being almost equally excreted by the kidney (unchanged form) and hepatic metabolism followed by biliary excretion. Organic cation transport is not as important as the organic anion pathway. Neutral compounds may employ the third transport systems. Ouabain, a cardiac glycoside, is used as a model uncharged and nonmetabolized (by rat liver) compound

Table 2.4 Mean bile flow in selected species

Species	Bile flow (ml/min/kg body weight)
Cat	11
Chicken	20
Dog	4–10

Rabbit	90
Rat	50–80
Sheep	43

in hepatobiliary transport studies. Organic anions and neutral steroids such as ouabain may share common mechanisms in their excretory pathways.

Molecular weight is a key determinant of the extent to which drug/metabolite molecules are transported into bile. The molecular weight cutoff required for biliary excretion is much greater than that for renal tubular secretion, being from 300 to 500 in most species. If the molecular weight is lower, the compound may be preferentially excreted in urine. Excretion of molecules larger than 850 Da occurs mainly via the biliary active transport system. However, molecular weight is not the sole factor determining the route of drug excretion. Physicochemical properties of the drug (polarity/lipophilicity, structure) are also very critical to the extent of biliary excretion of a drug/metabolite, with amphiphatic drugs being well secreted by the biliary route.

The specific animal species being studied is also an important factor, as reflected in different molecular weight cutoff thresholds. Table 2.4 lists species differences in bile flow rate that may also contribute to the great species specificity seen in biliary drug transport. Such variations in both a species' enzyme profile for biotransformation and inherent ability to excrete drugs in bile result in great difficulty in predicting hepatic clearance across drugs in different species.

Conclusion

This chapter presents an overview of some essential principles of ADME that are needed to understand drug- and species-specific behavior of drugs, examples of which are discussed in most chapters of this text. The next chapter focuses on the pharmacokinetic tools used to quantitate these processes so that safe and effective dosages of drugs can be administered to animals. There is a tremendous amount of research being conducted on the determinants of ADME processes because they are so important in assuring safety and efficacy of drugs across all species. They are the primary source of differences in drug action across species.

Pharmacokinetics

Jim E. Riviere

Pharmacokinetics is best defined as *the use of mathematical models to quantitate the time course of drug absorption and disposition in man and animals*. With the tremendous advances in medicine and analytical chemistry, coupled with the almost universal availability of computers, what was once an arcane science has now entered the mainstream of most fields of human and veterinary medicine. This discipline has allowed dosages of drugs to be tailored to individuals or groups to optimize therapeutic effectiveness, minimize toxicity, and avoid violative tissue residues in the case of food-producing animals. This subject and its concepts have become especially important as a consequence of the dramatic and almost radical changes that occurred at the end of the last decade relative to the regulations surrounding drug use in veterinary medicine in the United States. For most of the recent past, the operative concept was that a single dose of drug listed on a product label was optimal for all therapeutic uses. Recently, however, the legal concept of "flexible or professional labeling" and the passage by the US Congress in 1994 of the Animal Medicinal Drug Use Clarification Act (AMDUCA) legalizing extralabel drug use challenged this simplistic ideal of a single optimal dose. The veterinarian must now select a drug dose based on numerous factors inherent to the therapeutic scenario at hand to maximize therapeutic efficacy and minimize the likelihood of drug-induced toxicity or induction of microbial resistance. Furthermore, linking pharmacokinetic models to models of drug action, presented in the next chapter, allows for developing a quantitative link between dose and efficacy or toxicity. Unlike human medicine and companion animal practices, food animal veterinarians face the further restriction that proper withdrawal times must be determined to ensure that drug residues do not persist in the edible tissues or by-products (milk, eggs) of treated animals long after they have left the care of the veterinarian (Figure 3.1). As will be demonstrated and further discussed in Chapter 61, the "withdrawal time" is in reality a pure pharmacokinetic parameter since it can be calculated solely from a knowledge of the legal tissue tolerance and the drug's half-life or rate of decay in that tissue.

Yet it is not only the food animal veterinarian that faces these challenges. The laboratory animal and exotic/zoo animal worker must often extrapolate drug dosages across species with widely differing body sizes and physiology since there are very few approved drugs for the treatment of such animals. Pharmacokinetic principles and techniques are ideally suited for this application. Practitioners are often faced with disease processes (e.g., renal failure) that are known to affect the disposition of a drug. Knowledge of how such a pathological process affects a drug's clearance is sufficient knowledge to adapt a dosage regimen appropriate for this condition.

The previous chapter of this text presented the underlying physiology of drug fate. The processes involved in absorption, distribution, metabolism, and elimination are the primary phenomena that must be quantitated to predict the fate of a drug or toxicant in an animal. The two primary characteristics needed to adequately describe these processes are their *rate* and *extent*. In fact, this can be appreciated in the origin of the word *kinetic,* which is defined as: "*of or resulting from motion*." Many mathematical approaches to this problem have evolved over the course of the history of pharmacokinetics. The reader is suggested to consult the selected readings for more in depth presentations of pharmacokinetic modeling. In addition, hybrid as well as novel strategies are constantly being developed to quantitate these processes. However, all approaches share certain fundamental properties that are based upon estimating the rates of chemical movement.

A Primer on the Language of Pharmacokinetics

The roots of pharmacokinetics lie in the estimation of rates. The language is that of differential calculus. It is instructive to briefly overview the basic principles of rate

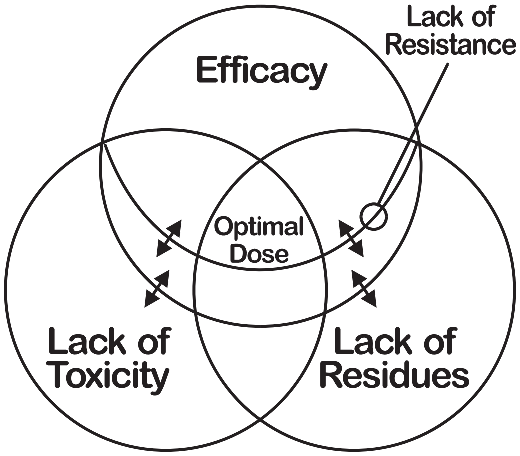

Figure 3.1 The food animal veterinarian's dilemma in optimizing the dose of a therapeutic drug.

determination since the logic imbedded in its syntax forms the basis of pharmacokinetic terminology.

To begin, a *rate* in pharmacokinetics is defined as *how fast the mass of a compound changes per unit of time*, which is expressed mathematically as the change (represented by the Greek letter delta, Δ) in mass per small unit of time (Δt). This is synonymous with the flux of drug in a system. Units of rate are thus mass/time. For the sake of convenience only, we will express this in terms of mg/min. We will begin this discussion using mass of a compound (X), which in clinical terms would be related to the dose, rather than using concentration. As will be developed shortly, mass and concentration are easily convertible using the proportionality factor of volume of distribution.

The rate of drug excretion ΔX/Δt actually has two components, a constant that reflects the rate of the process and the amount of compound available for transfer (Equation 3.1):

$$\Delta X/\Delta t = KX^n \tag{3.1}$$

where K is the fractional rate constant (1/min), X (mg) is the mass or amount of a compound available for transfer by the process being studied, and n is the order of the process.

For a first-order process, n = 1. Since $X^1 = X$, this equation simplifies to Equation 3.2:

$$\Delta X/\Delta t = KX \tag{3.2}$$

By definition, in this first-order (n = 1) or linear processes, K is *constant* and thus *the actual rate of the process ($\Delta X/\Delta t$) varies in direct proportion (and hence linearly) to X*. K can be viewed as the fraction of X that moves in the system being studied (absorbed, distributed, or eliminated) per unit of time. Therefore, as X increases, ΔX/Δt increases in direct proportion. In linear models, the rate constant is fixed but the rate of the process changes in direct proportion to the mass available for movement.

As can again be appreciated by examining the equation for Fickian diffusion (Equation 2.1 in Chapter 2), compounds that are either absorbed, distributed, or eliminated in direct proportion to a concentration gradient are by definition first-order rate processes. The rate constants (K_n) modeled in pharmacokinetics are actually aggregate constants reflecting all of the membrane diffusion and transfer processes involved in the disposition parameter being studied. This includes pH partitioning phenomena in the body, which exist when blood and a cellular or tissue compartment have a pH gradient that alters the fraction of drug available for diffusion. Recall that it is only the unionized fraction of a weak acid or base that diffuses down its gradient across a lipid membrane. The rate constant also reflects the degree of plasma protein binding since only the free fraction of drug is available for distribution. The actual value of a K in a pharmacokinetic model thus reflects all of these variables whose relationship defines the biological system that we are attempting to quantitate.

For a nonlinear or zero-order process, by definition n = 0. Since $X^0 = 1$, the rate equation now becomes

$$\Delta X/\Delta t = K_0 \tag{3.3}$$

In this scenario, the *rate of excretion is fixed and thus independent of the amount of compound available, X*. K_o now has the units of rate (mg/min) and is *not* a mass-independent fractional rate constant. Although this would appear to simplify the situation, in reality nonlinear kinetics actually complicate most models. Nonlinear behavior becomes evident when saturation of a process occurs. The focus of most pharmacokinetic studies is on drugs with linear pharmacokinetics since the majority of therapeutically active compounds are described by these models.

The use of ΔX/Δt to describe the rate of a process is experimentally and mathematically cumbersome, since ΔX/Δt changes as a function of concentration. Figure 3.2 graphically depicts this scenario. Calculus has been used to describe these same processes using the concept of a derivative. Instead of describing rates in terms of some small, finite time interval (Δt), differential equations express rate in terms of the change in compound mass over an infinitesimally small time interval termed dt. Equation 3.1 could now be written as the following (Equation 3.4):

$$dX/dt = -KX \tag{3.4}$$

The biological interpretation is identical. Note that K and X are the same in both equations; the only change is a conceptual one in that *dX/dt* now describes the instantaneous rate of change in mass over time. By convention, if the amount of drug is increasing, dX/dt is positive (e.g.,

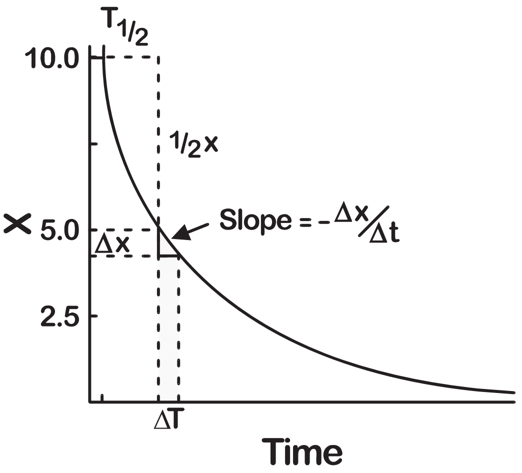

Figure 3.2 Plot of the decay in drug (X) versus time. The T1/2 is defined as the time required for X to deplete to 1/2 X. Slope at any time is ΔX/ΔT.

absorption of drug into the blood); if it is declining (e.g., elimination or distribution from the blood), the rate is negative or −dX/dt.

One may solve a differential equation through the process of integration ($\int$), which transforms the equation back into terms of t rather than dt. Integration is in reality a process by which the area under the curve (AUC) defined by ΔX/Δt is taken. By repeatedly summing these areas for the entire experimental period, the area under the curve will be obtained. We introduced this concept in Equation 2.4 when the concept of AUC was introduced. Analogous to the relation of a derivative to a slope, integration sums the areas under infinitesimally small regions defined by dX/dt.

We can use the technique of integration to solve the rate Equation 3.4. We must integrate the equation from X at time zero (X_0) through X at time t (X_t) to obtain a formula for the mass of drug at any time (Equation 3.5):

$$\int_0^t \left(\frac{dX}{dt}\right) dt = \int_0^t (-KX)\ dt \tag{3.5}$$

There are numerous techniques to accomplish this integration and the interested reader should consult a calculus textbook for further details. The result is the following (Equation 3.6):

$$X_t = X_0 e^{-Kt} \tag{3.6}$$

where *e* is the base of the natural logarithm (e = 2.713). *It is important to realize that the process of integrating the differential equation describing rate generates the exponential term found in most linear pharmacokinetic models.* Exponentials can easily be eliminated from an equation by taking their natural logarithm (*ln*) since the logarithm is defined as the power to which a base (in this case *e*) is raised. Taking the natural logarithms of Equation 3.6 yields the following (Equation 3.7):

$$\ln X_t = \ln X_0 - Kt \tag{3.7}$$

If one plots these data, a straight line results, as seen in Figure 3.3, which is much easier to deal with than the curve in Figure 3.2. Recalling the algebraic expression for a straight line on x–y coordinates, in this case the y intercept becomes X_0 and the slope of the line is −K. The equation has been linearized providing a simple graphical method to calculate the rate constant.

This equation can be linearized because it is a first-order rate function. This type of plot, which is widely used throughout pharmacokinetics, is termed a semilogarithmic plot (in contrast to the Cartesian plot) since the logarithm of mass is plotted against time. Again, *when a straight line results on a semilogarithmic plot, one can assume that a linear first-order process is operative and the slope of the line is the exponent of an exponential equation.* Alternatively, a linear regression program on a computer or calculator could be used to calculate K by regressing the ln X against time; the slope is −K and the y intercept is $\ln X_0$. In earlier work, graph paper was used that plotted logarithms to the base 10 (log x) $\{10^x\}$ rather than the base e (ln x) $\{e^x\}$ where x is the logarithm, the transformation of bases can be accomplished as the following (Equation 3.8):

$$\log X = \ln X/2.303 \tag{3.8}$$

which transforms Equation 3.7 to

$$\log X_t = \log X_0 - Kt/2.303 \tag{3.9}$$

If base 10 semilogarithmic graph paper is used to plot Figure 3.3, the slope becomes −K/2.303. As this technique was in widespread use before the advent of digital computers, this is still encountered in older manuscripts and texts.

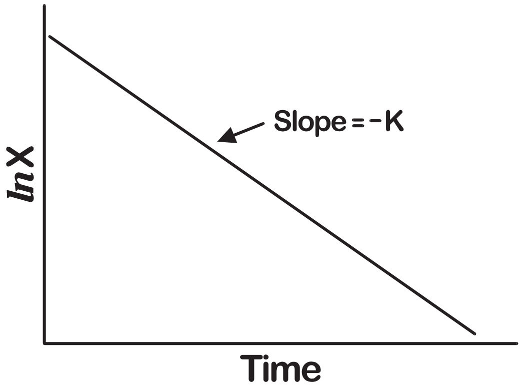

Figure 3.3 Semilogarithmic plot of drug decay versus time with slope equal to −K.

The Concept of Half-Life

The exponential equations in pharmacokinetics have another property that is important to biological applications. This is the concept of half-life (T1/2) whose logic is central to much of this discipline. The astute biologist reading this text will have realized that Equation 3.6 is the same as that used to describe population doubling times in microbiology or ecology and used to generate population growth curves, defined as the time needed for a population of organisms to double their total numbers when they are in their so-called *logarithmic* growth phase. The only difference is that since growth is described, the exponent is positive in this application. In pharmacokinetics, our perspective is decay with a T1/2 instead being the time required for the amount of drug to decrease by one-half or 50%. The concept of T1/2 is applicable only to first-order rate processes.

Using Equation 3.7, one can derive a simple equation for T1/2. We first rearrange terms to solve for T, which yields

$$T = (\ln X_0 - \ln X_t)/K \tag{3.10}$$

We now solve for the time at which X_t is equal to 1/2 the initial amount X_0, that is, where $T =$ T1/2. Substituting these values, the equation reduces to

$$K = 0.693/T{}^{1}\!/_{2}. \tag{3.11}$$

It is this transformation of K with T1/2 that introduces the ln 2 or 0.693 into many pharmacokinetic equations.

What does T1/2 really mean? Assume that we start with X, decrease it by half, and repeat this process 10 times. Table 3.1 compiles this data and lists how much drug is remaining and how much has been excreted over each Δt corresponding to one T1/2. Note that if you sum these columns, you would have accounted for 99.9% of the original dose X. After 10 T1/2s, 99.9% of the drug has been eliminated or the rate process being studied has been completed. This also illustrates the logic that must be used when dealing with doses. For example, if you double the dose to 2×, then after one T1/2 you would be back to the original dose! Many rules of thumb used in pharmacokinetics and medicine are based on this simple fact. For therapeutic drugs, most workers assume that after five T1/2s, the drug has been depleted or the process is over since 97% of the depletion has occurred. This also illustrates a very simple way to calculate T1/2, by simply determining the time required for drug concentration to decrease by 50%. This was depicted in Figure 3.2. Equation 3.11 can then be used to obtain K. It now is time to develop our first pharmacokinetic model using mathematical rather than physiological concepts.

Table 3.1 Relationship of T1/2 and amount of drug (A) in the body

Number of T1/2s	% of Drug remaining	% of Drug eliminated
1	50	50
2	75	25
3	87.5	12.5
4	93.75	0.625
5	96.88	0.312
6	98.44	0.156
7	99.22	0.078
8	99.61	0.039
9	99.80	0.019
10	99.90	0.0097

One-Compartment Open Model

The most widely used modeling paradigm in comparative and veterinary medicine is the compartmental approach. In this analysis, the body is viewed as being composed of a number of so-called equilibrium compartments, each defined as representing nonspecific body regions *where the rates of compound disappearance* are of a similar order of magnitude. Specifically, the fraction or percent of drug eliminated per unit of time from such a defined compartment is constant. Such compartments are classified and grouped on the basis *of similar rates of drug movement* within a kinetically homogeneous but anatomically and physiologically heterogeneous group of tissues. These compartments are theoretical entities that allow formulation of mathematical models to describe a drug's behavior over time with respect to movement within and between compartments. Since pharmacologists and clinicians sample blood as a common and accessible biological matrix for assessing drug fate, most pharmacokinetic models are constructed with blood or plasma drug concentrations as the central reference to which other processes are related.

The simplest compartment model is when one considers the body as consisting of a single homogeneous compartment; that is, the entire dose X of drug is assumed to move out of the body at a single rate. This model, depicted in Figure 3.4, is best conceptualized as instantly dissolving and homogeneously mixing the drug in a beaker from which it is eliminated by a single rate process described by the rate constant K, now termed K_{el}. Since the drug leaves the system, the model is termed *open*. Equation 3.6 is the pharmacokinetic equation for the one-compartment open model. Although expressed in terms of the amount of drug remaining in the compartment, most experiments measure concentrations. This requires the development of the volume of distribution (Vd) (recall Equation 2.5 when distribution was discussed). In terms of the one-compartment model, this would be the volume of the compartment into which the dose of drug (D) instantaneously distributes. *Vd*

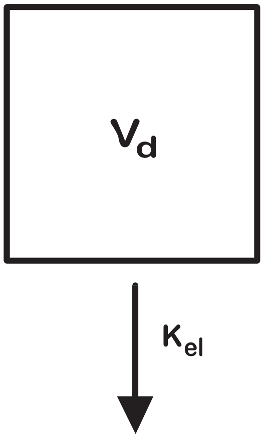

Figure 3.4 One-compartment open pharmacokinetic model.

thus becomes a *proportionality factor* relating *D* to the observed concentration *Cp* by

$$Vd\ (ml) = X\ (\cancel{mg})/Cp\ (\cancel{mg}/ml) = D/Cp \qquad (3.12)$$

Using this relation, we can now rewrite Equation 3.6 in terms of concentrations, which are experimentally accessible by sampling blood, instead of the total amount of drug remaining in the body.

$$Cp = X_0/Vd\ e^{-Kelt} = Cp_0 e^{-Kelt} \qquad (3.13)$$

A semilogarithmic plot seen after intravenous administration using this model is depicted in Figure 3.5. Vd quantitates the apparent volume into which a drug is dissolved, since, recalling the discussion in Chapter 2, the true volume is determined by the physiology of the animal, the relative transmembrane diffusion coefficients, and the chemical properties of the drug being studied. A drug that is restricted to the vascular system will have a very small Vd; one which distributes to total body water will have a very large Vd. In fact, it is this technique that is used to calculate the plasma and interstitial spaces.

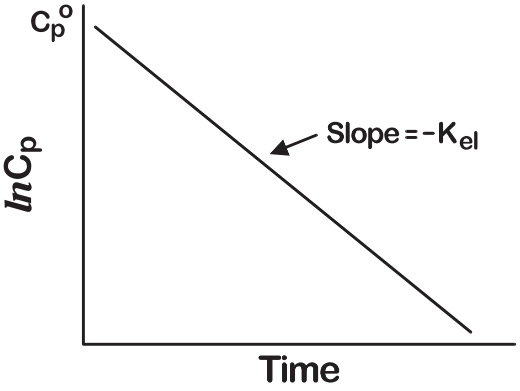

Figure 3.5 Semilogarithmic concentration-time profile for a one-compartment drug with slope $-K_{el}$ and intercept Cp_0.

From this simple analysis, and using the model in Figure 3.4, a number of useful pharmacokinetic parameters may be defined. Assuming that an experiment such as depicted in Figure 3.5 has been conducted using a dose of D and values for K_{el} and Vd have been determined, T1/2 can easily be calculated from Equation 3.11 above.

Clearance

Recalling the development of clearance concepts in Chapter 2, we now can easily determine Cl_B using this information. Clearance was defined as *the volume of blood cleared of a substance by the kidney per unit of time.* If one considers the whole body, this would read as *the volume of distribution of drug in the body cleared of a substance per unit of time.* Translating this sentence to the syntax of pharmacokinetic terminology and considering whole body elimination, Vd represents the volume and K_{el} the fractional rate constant (units of 1/time). Thus clearance is

$$Cl_B(ml/min) = Vd)ml)\ K_{el}(1/min) \qquad (3.14)$$

There is another method available to calculate Cl_B. In Chapter 2, clearance was also defined in Equation 2.8 as *the rate of drug excretion relative to its plasma concentration*. We can also express this sentence in the syntax of pharmacokinetics and get this relation:

$$Cl_B = (dX/dt)/Cp \qquad (3.15)$$

If we integrate both the numerator and denominator of this relation from time 0 → ∞, the numerator is the sum of the total amount of drug which has been excreted from the body; that is, assuming intravenous administration, the administered dose D. The denominator is the integral of the plasma concentration time profile the area under the curve (AUC). The relation thus becomes:

$$Cl_B = D/AUC \qquad (3.16)$$

There are two approaches to calculate AUC. A common approach is to use the trapezoidal method depicted in Figure 3.6. However, for the one-compartment model that generates the semilogarithmic C-T plot depicted in Figure 3.5, the problem is simply determining the area of the right triangle. The area of this triangle (AUC) is height divided by the slope of the hypotenuse, or:

$$AUC = Cp_0/K_{el} \qquad (3.17)$$

Interpretation of Pharmacokinetic Parameters

With these equations, we now have the three so-called *primary pharmacokinetic* parameters describing drug disposition in the body: *T*1/2, Cl_B, and *Vd.* The data required to calculate them is a knowledge of dose and an experimental derivation of either K_{el} or T1/2.

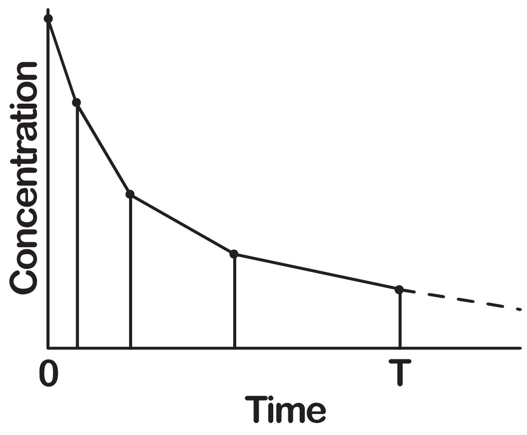

Figure 3.6 Trapezoids formed from sampled concentration versus time data for calculation of areas. To estimate the total AUC, the curve must be extrapolated beyond the ultimate sample time, T, to infinity (—).

This is a good place to discuss the limits of calculating parameters from such simple concentration-time profiles. Only two parameters are actually being "measured" from this analysis: the slope K_{el} and intercept Cp_0 of the semilogarithmic plot, which – using Equation 3.12 directly – determines Vd. The third parameter Cl is "calculated" from the two measured parameters. Based on the mathematical method used to calculate these, some workers suggested that K_{el} and Vd are the independent parameters in a pharmacokinetic analysis and Cl is a derived parameter. This assertion is usually made when the statistical properties of the parameters are being defined since errors for these can be easily obtained. However, this belief is an artifact of the use of a compartmental model as a *tool* to get at values for these physiological parameters. Biologically, the truly independent parameters are the Vd and Cl, with K_{el} and thus T1/2 becoming the dependent variables. From this biological perspective, the true relationship is

$$T1/2 = (0.693 \times Vd)/Cl \tag{3.18}$$

The observed half-life of a drug is dependent upon *both* the extent of a drug's distribution in the body *and* its rate of clearance. If the clearance of a drug is high (e.g., rapidly eliminated by the kidney), the T1/2 is relatively short. Logically, a slowly eliminated drug will have a prolonged T1/2. Not obvious at first is that if a drug is extensively distributed in the body (e.g., lipid-soluble drug distributed to fat), Vd will be large *and* the T1/2 will also be relatively prolonged. In contrast, if a drug has restricted distribution in the body (e.g., only the vascular system), the Vd will be small, a large fraction of the drug will be available for elimination, and thus the T1/2 relatively short. In a disease state, T1/2 may be prolonged by either a diseased kidney, a reduced capacity for hepatic drug metabolism, or an inflammatory state, which increases capillary perfusion and permeability, thus allowing drug access to normally excluded tissue sites. Therefore, T1/2 is physiologically dependent on both the volume of distribution and clearance of the drug.

Cl_B is the sum of clearances from all routes of administration:

$$Cl_B = Cl_{Renal} + Cl_{Hepatic} + Cl_{other} \tag{3.19}$$

There is another strategy that can be used to estimate clearance in an intravenous study. This is based on the basic principle of mass balance. The strategy is to infuse a drug into the body at a constant rate R_o (mass/time) and then measure plasma drug concentrations. By definition, when a steady-state plasma concentration is achieved, C^{ss} (mass/volume), the rate of drug input must equal the rate of clearance from the body, Cl_B:

$$R_o\ (mg/\text{min}) = C^{SS}\ (mg/\cancel{ml}) \times Cl\ (\cancel{ml}/\text{min}) \tag{3.20}$$

Rearranging this equation gives a simple formula for determining Cl:

$$\begin{aligned} Cl\ (ml/\text{min}) &= R_o\ (\cancel{mg}/\text{min})/C^{SS}\ (\cancel{mg}/ml) \\ &= R_o/C^{SS}\ (ml/\text{min}) \end{aligned} \tag{3.21}$$

The Cl calculated in this manner is identical to that determined using Equations 3.14 and 3.16 above, and requires only knowing the rate of infusion and assaying the achieved steady-state concentration. One may also calculate the Vd from an intravenous infusion study by the relation:

$$Vd = R_0/C^{SS}K_{el} \tag{3.22}$$

Many of the pharmacokinetic parameters above may also be obtained by analysis of urine data alone, an approach beyond the focus of the present introduction.

Absorption in a One-Compartment Open Model

The analysis above assumes that the drug was injected into the body, which behaves as a single space into which the drug is uniformly dissolved. The first real-world complication is when the drug is administered by one of the extravascular routes discussed in Chapter 2. In this case, the drug must be absorbed from the dosing site into the bloodstream. The resulting semilogarithmic concentration–time profile, depicted in Figure 3.7, now is characterized by an initial rising component that peaks and then undergoes the same log-linear decline. The proper pharmacokinetic model for this scenario is depicted in Figure 3.8. The rate of the drug's absorption is governed by the rate constant K_a. When the absorption process is finally complete, elimination is still described by K_{el} as depicted in Figure 3.5. The overall elimination half-life can still be calculated using K_{el} if this terminal slope is taken after the peak (C^{max}) in the linear portion of

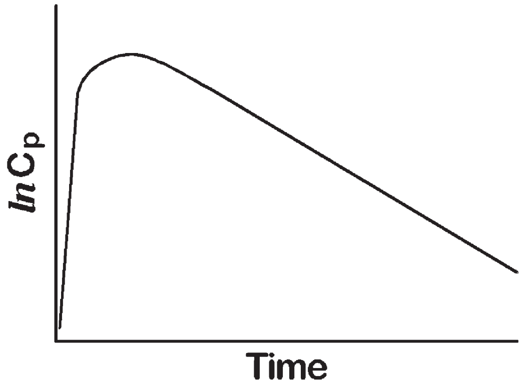

Figure 3.7 Semilogarithmic plot of plasma concentration versus time with first-order absorption.

the semilogarithmic plot (providing $K_a \gg K_{el}$). However, calculation of Vd and Cl becomes more complicated since K_a is present and, unlike an intravenous injection, one is not assured that all of the drug has been absorbed into the body. In order to handle this, we must now write the differential equations to describe this process by including rate constants for absorption and elimination:

$$dX/dt = K_aD - K_{el}X \tag{3.23}$$

where *D* is the administered dose driving the absorption process and *X* is now the amount of dose absorbed and available for excretion. The relationship between D and X is the absolute systemic availability F originally introduced in Equation 2.4 [X = FD]. In the language of differential equations, rates are simply additive, which allows the same data sets to be described in components reflecting the different processes. As above, integrating this equation and expressing it in terms of concentrations, gives the expression that describes the profile in Figure 3.9:

$$C = \frac{K_aFD}{Vd\,(K_a - K_{el})}\,[e^{-K_{el}t} - e^{-K_at}] \tag{3.24}$$

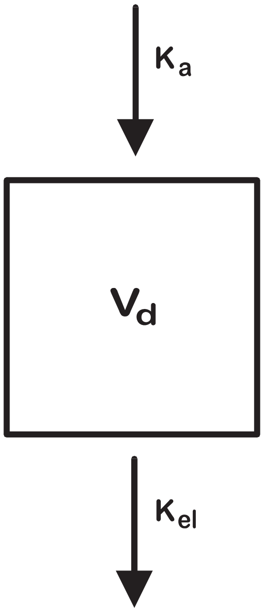

Figure 3.8 One-compartment open pharmacokinetic model with first-order absorption.

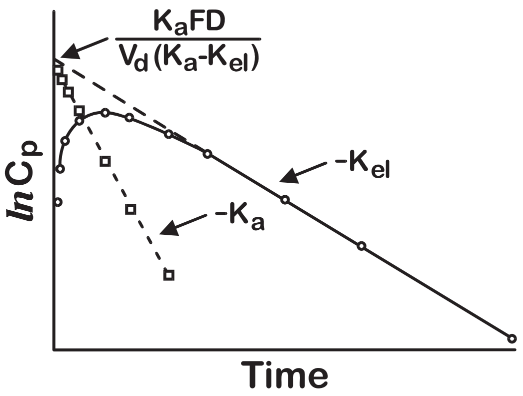

Figure 3.9 Semilogarithmic plot of plasma concentration versus time using a one-compartment open pharmacokinetic model with first-order absorption. The profile is decomposed into two lines with slopes $-K_a$ and $-K_{el}$.

This is an excellent point in the discussion to appreciate the validity of the use of multiexponential equations to describe blood C-T profiles as the exponential terms, which, like the rates above from which they were derived, are simply additive. A C-T profile is the sum of the underlying exponential terms describing the rate processes involved. This property of superposition is the basis upon which observed C-T profiles may be "dissected" to obtain the component rates. Figure 3.9 illustrates this process where an observed semilogarithmic profile is plotted as a composite of its absorption phase (controlled by K_a) and the elimination phase (controlled by K_{el}). In contrast to the intravenous scenario, the time zero intercept is now a more complex function, which is dependent upon the fraction of administered dose that is systemically available and thus able to be acted on by the elimination process described by the rate constant K_{el}. For this procedure to work, K_a must be greater than K_{el} so that at later time points e^{-Kat} approaches zero. If $K_a < K_{el}$, the same C-T profile will result; however, now the terminal slope will be K_a as it is the rate-limiting process! One just "*flip-flopped*" K_a for K_{el}. In fact, recalling the discussion in Chapter 2 on slow-release dosing formulations, we termed the resulting effect on disposition of drug in the body an example of the *flip-flop* phenomenon, the origin of which is this relation. When an extravascular route of administration is used, one can never be certain that the C-T profile is not dependent upon a slow, and thus rate-limiting, absorptive process secondary to a formulation factor. If a depot or slow-release formulation is administered such that $K_a < K_{el}$, the terminal slope will reflect the rate of absorption rather than the rate of elimination. T1/2 may be overestimated as it will now reflect $0.693/K_a$ rather than $0.693/K_{el}$. Complete absorption also cannot be assured (e.g., $F = 1$); thus one never truly knows the size of the absorbed dose. Accurate estimates of Cl and Vd, reflecting the true pharmacokinetic disposition of a drug, are required as input to determine these relations. These are best calculated after a complete intravenous injection. Finally, as discussed above for intravenous administration, urine analysis may also be used to estimate absorption parameters.

As we leave this section, it is a good time to underscore the relationship of some ADME processes as they translate to pharmacokinetic parameters; namely absorption, clearance, and volume of distribution, and further relate to the main determinants of a dosage regimen – namely, F and T1/2. This can be appreciated as

Absorption Clearance Distribution
F T1/2

F was determined by Equation 2.4 as the ratios of AUC_{oral}/AUC_{iv}. The intravenous D is a function of Cl and AUC from Equation 3.16. Half-life was a function of Vd and Cl in Equation 3.18. This scheme shows how F is a function of absorption and clearance processes (AME) while half-life is a function of clearance and distribution (DME).

Why are these relationships important? One of the main clinical applications of pharmacokinetic principles is to construct dosage regimens, the approach that is fully presented below. Diseases that change any of these primary pharmacokinetic parameters would be expected to change the plasma concentrations achieved after dosing, and thus drug effect. For example, renal disease that reduced GFR, might reduce Cl_B for drugs primarily eliminated by the kidney. Similarly, liver disease might alter disposition of drugs cleared by the liver. In contrast, diseases that resulted in severe elimination and fluid accumulation could alter Vd. Both of these scenarios would increase T1/2 and alter plasma concentrations. The relationship between concentration and effect is extensively discussed in the next chapter on pharmacodynamics.

Two-Compartment Models

Many drugs are not described by a simple one-compartment model since the plasma concentration time profile is not a straight line. This reflects the biological reality that for many drugs, the body is not a single homogeneous compartment, but instead is composed of regions that are defined by having different *rates* of drug distribution. Such a situation is reflected in the two-compartment model depicted in Figure 3.10. The drug initially is distributed in the central compartment and by definition is eliminated from this compartment. The difference comes because now the drug also distributes into other body regions at a rate that is different from that of the central compartment.

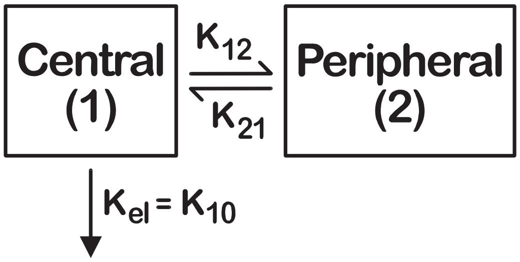

Figure 3.10 Generalized open two-compartment pharmacokinetic model after intravenous administration with elimination (K_{el}) from the central compartment. K_{12} and K_{21} represent intercompartmental micro-rate constants.

As presented in Chapter 2, there are many factors that determine the rate and extent of drug distribution into a tissue (e.g., blood flow, tissue mass, blood/tissue partition coefficient, etc.). When the composite rates of these flow and diffusion processes are significantly different than K_{el}, then the C-T profile will reflect this by assuming a biexponential nature. For many drugs, the central compartment may consist of blood plasma and the extracellular fluid of highly perfused organs such as the heart, lung, kidneys, and liver. Distribution to the remainder of the body occurs more slowly, which provides the physiological basis for a two-compartment model. Such a peripheral compartment is defined by a distribution rate constant (K_{12}) out of the central compartment and a redistribution rate constant (K_{21}) from the peripheral back into the central compartment. As discussed in the distribution chapter, depots or sinks may also occur. This is a pharmacokinetic concept where the distribution rate constants are significantly slower than K_{el} and thus become the rate-limiting factor defining the terminal slope of a biexponential C-T profile, a situation analogous to flip-flop in absorption studies.

We will begin the discussion of multicompartmental models with the principles of analyzing a two-compartment model after intravenous administration (Figure 3.11). This is the most common scenario encountered in comparative medicine and the principles easily translate to more complicated models. The fundamental principle involved is that the observed serum concentration time profile is actually the result of two separate pharmacokinetic processes that can be described by two separate exponential terms, commonly written as:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \tag{3.25}$$

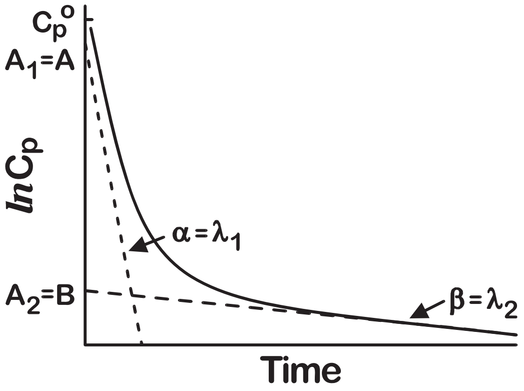

Figure 3.11 Semilogarithmic plasma concentration versus time profile of a drug described by a two-compartment open model. Parameters are defined in the text.

Note the similarity of this biexponential equation to that presented for absorption in Equation 3.24. In this case we have terms with slopes (α and β) and corresponding intercepts (*A* and *B*). The C-T profile on semilogarithmic plots is depicted in Figure 3.11. By definition, $\alpha \gg \beta$ and thus β is the terminal slope. If $\alpha \approx \beta$, the slopes of the two lines would be equal and we would be back to the single line of Figure 3.5 and a one-compartment model!

When dealing with multicompartmental models, it becomes necessary to introduce new nomenclature to denote the intercept terms and slopes of the C-T profile because, as will be shown shortly, the observed slopes are no longer synonymous with the elimination and distribution micro-rate constants as they were when we were analyzing absorption plots for K_{el} and K_a. When these models were constructed, the defining differential rate equations could be written in terms of the mass of drug in the central compartment (X). In the two-compartment model of Figure 3.10, this equation now must describe drug movement in terms of the mass of drug in compartment one and two. The solution to these differential equations are the slopes of the biexponential C-T profile giving α and β. Multicompartmental models have their own syntax: the slopes of the C-T profile are named using the Greek alphabet, starting with the most rapid rate α for distribution followed by β for elimination. The intercept terms are denoted using the Roman alphabet as A related to α and B to β.

A preferred nomenclature carries less phenomenological context and uses the Greek letter λ_n, with $n = 1, 2, 3, \ldots$ progressing from the most rapid to the slowest rate process. The corresponding intercept terms are denoted as A_n. This nomenclature describes any multicompartmental model without implying a physiological basis to the underlying mechanism responsible for the different rates observed. The biexponential equation for a two-compartment model may now be written as

$$Cp = A_1 e^{-\lambda_1 t} + A_2 e^{-\lambda_2 t} \tag{3.26}$$

The actual rate constants describing flux between compartments are now termed micro-rate constants and denoted by k_{xy}, where compound moves from $x \rightarrow y$. When the origin or destination of a compound is outside of the body, x or y is denoted as 0, respectively. K_a thus becomes k_{01} and K_{el} becomes k_{10}. With a two-compartment model, three Vds may be calculated: the volume of the central compartment V_c or V_1, the peripheral compartment V_p or V_2, and the total volume of distribution in the body V_t or $V_1 + V_2$. As will be seen below, the actual Vd calculated from the data is dependent upon the method used; however, the only estimate of V_t which can be broken into its component central and peripheral volumes is the volume of distribution at steady state, Vd_{ss}.

Now that we have the appropriate nomenclature, it is instructive to derive the differential rate equations for λ_n and A_n based on the microconstants which define them. For a two-compartment model after intravenous injection of dose D with elimination occurring from the central compartment, the following differential equation describes the rate of drug disposition:

$$dC_1/dt = -(k_{12} + k_{10})C_1 + (k_{21})C_2 \tag{3.27}$$

Processes that remove compound from the central compartment (k_{10} and k_{12}) are grouped together and have a negative rate since they result in a descending C-T profile. The only process that adds chemical to the central compartment (k_{21}) – that is, redistribution from the peripheral compartment – is assigned a positive rate and results in an ascending C-T profile. The rate of this process is driven by the concentration of compound in the peripheral compartment. Note the similarity of this equation to the differential equation for absorption in a one-compartment model (Equation 3.23). In this model, the only process that added drug to the central compartment was k_a, which therefore was assigned a positive sign, while the only process removing drug was $-K_{el}$. Similarly, as stressed throughout this text, the driving mass for this passive absorption process was the fraction of administered dose (F X) available for absorption. The power and essence of pharmacokinetic analysis is that the physiological processes driving drug disposition can be quantitated by using differential equations describing drug flux into and out of observable compartments, with most models structured to reflect the central compartment, which is monitored via blood sampling as the primary point of reference. Solution of the differential Equation 3.27 by integration yields Equations 3.25 or 3.26 describing the biexponential C-T profile characteristic of a two-compartment open model.

The observed slopes λ_1 and λ_2 and intercepts A_1 and A_2 are related to the microconstants as

$$k_{21} = (A_1\lambda_2 + A_2\lambda_1)/(A_1 + A_2) \qquad (3.28)$$

$$k_{el} = \lambda_1\lambda_2/k_{21} \qquad (3.29)$$

$$k_{12} = \lambda_1 + \lambda_2 - k_{21} - k_{10} \qquad (3.30)$$

Similarly, each of the slopes now has a corresponding T1/2 calculated as

$$T1/2\lambda_1 = 0.693/\lambda_1 \quad \{\text{Distribution}\} \qquad (3.31)$$

$$T1/2\lambda_2 = 0.693/\lambda_2 \quad \{\text{Elimination}\} \qquad (3.32)$$

The slope of the terminal phase of the C-T profile reflects the elimination T1/2 and is the primary parameter used to calculate dosage regimens. Note that since $\gamma_1 \gg \gamma_2$, $T1/2_{\gamma 1} \ll T1/2_{\gamma 2}$ and at later time points (recall the five T1/2 rule), distribution will be complete and the biexponential Equation 3.26 collapses to the monoexponential equation $Cp = A_2e^{-\lambda 2t}$. This equation is similar in form to the one-compartment Equation 3.13 except the intercept is now A_2 and not Cp_0 and the slope is $-\gamma_2$ and not K_{el}. This property of "disappearing" exponentials with large γs at later time points provides the basis for analyzing polyexponential C-T profiles using the curve "stripping" approach (technically called the method of residuals) discussed earlier.

It is often difficult to accurately estimate distribution parameters when γ_1 is very rapid since early blood samples must be collected, sometimes before blood has completely circulated. In a large animal such as a horse or cow, this requires a few minutes and thus very early samples (e.g., <5 minutes) will not have sufficient time for this mixing to occur. Secondly, small errors in sample timing result in a large % error (1 minute off for a 5-minute sample; error is 20%) and thus the data obtained at very early time points is often extremely variable. In contrast, 5 minutes off of a 6-hour sample is only a 1% error making estimates of terminal slopes much less variable.

Volumes of Distribution

There are now three volumes of distribution to contend with: V_c or V_1, V_p or V_2, and $V_t = (V_1 + V_2)$. These are again calculated by a knowledge of intercepts and administered dose (assuming intravenous administration). The relevant intercept is $C_p{}^0$, which is now simply $A_1 + A_2$:

$$V_1 = D/C_p^0 = D/(A_1 + A_2) \qquad (3.33)$$

$$Vd_{ss} = V_1[(k_{12} + k_{21})/k_{21}] \qquad (3.34)$$

$$V_2 = Vd_{SS} - V_1 \qquad (3.35)$$

$$Vd\ (B) = D/B = D/A_2 \qquad (3.36)$$

$$Vd_{area} = D/[(AUC)(\lambda_2)] = D/[(AUC)(\beta) \qquad (3.37)$$

$$= Vd_\beta = (k_{10}V_1)/\lambda_2 \qquad (3.38)$$

The relation between these estimates are

$$Vd\ (B) > Vd_{area} > Vd_{SS} > V_C \qquad (3.39)$$

The easiest to discard is *Vd(B)*, the apparent volume of distribution by extrapolation, since it is often used when a complete analysis of the curve is avoided and only the terminal slope and its intercept A_2 is determined. As discussed above, this estimate completely ignores $V_{1.}$ Similarly, V_c is defined as only the central compartment volume. It is the volume from which clearance is determined and is used in some infusion calculations.

The volume of distribution at steady-state, Vd_{ss}, is the most "robust" estimate since it is mathematically and physiologically independent of any elimination process or constant. It is the preferred Vd estimate for interspecies extrapolations and the study of the effects of altered physiology on Vd since it is independent of elimination. Theoretically, Vd_{ss} describes the Vd at only a single time point when the rate of elimination equals that of distribution. The point at which this occurs is the inflection point or bend in the C-T profile that occurs because the more rapid tissue distribution phase has now peaked. This is best appreciated in Figure 3.12 when the concentrations in the central and tissue compartments are plotted.

Vd_{area} is often used when clinical dosage regimens are constructed because it reflects the area during the elimination phase of the curve which predominates in any dosage regimen (see Figure 3.12). This is absolutely equivalent to Vd_β, the so-called volume of distribution at pseudodistribution equilibrium. If the rate of elimination is very prolonged (slow), as seen in severe renal disease, the terminal slope of the concentration-time profile may

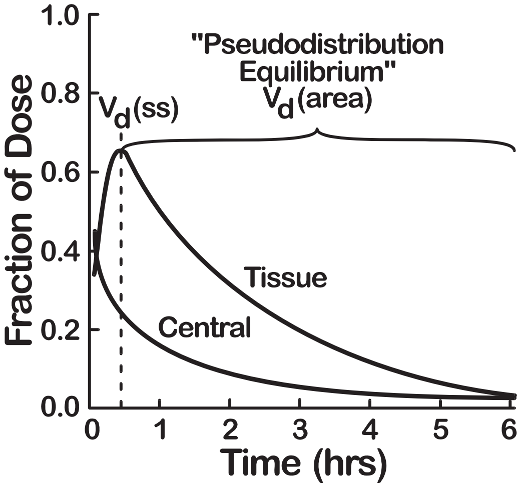

Figure 3.12 Relationship between Vd_{ss} and Vd_{area} for a drug described by a two-compartment model. Note that Vd_{ss} is only descriptive of the volume of distribution at the peak of the tissue compartment concentration versus time profile, while Vd_{area} describes the volume throughout the terminal elimination phase.

approach zero (plateaus; T1/2 becomes very long), which effectively "stretches out" the curve's inflection due to a plateau in the peripheral tissue compartment. Under this scenario, Vd_{area} becomes equal in value to Vd_{ss}.

Physiologically, a way to conceptualize Vd is to compare the individual compartment volumes based on plasma versus tissue binding, as:

$$Vd = V_{plasma} + V_{tissue}(fu_{plasma}/fu_{tissue}) \tag{3.40}$$

This relationship nicely shows the effect that both plasma and tissue protein binding can have on volume of distribution. Note that V_{plasma} and V_{tissue} do not directly correspond to V_1 and V_2, respectively, as the latter are determined by relative rates since both volumes actually include plasma and tissue.

Clearance

Knowing V_1, one can easily calculate the systemic clearance since Cl_B occurs from the central compartment and is essentially the same as a one-compartment model.

$$Cl = K_{10} V_1 \tag{3.41}$$

Alternatively, Cl_B may be calculated using the model-independent intravenous infusion Equation 3.21 presented earlier. The only difference is that with the more complex distribution kinetics present in a multicompartmental model, the time to reach C^{ss} may be significantly longer. Finally, Cl_B may also be determined using Equation 3.16 based on AUC. In a two-compartment model, AUC may be calculated using slopes and intercepts by the relation

$$\mathrm{AUC} = (A_1/\lambda_1) + (A_2/\lambda_2) \tag{3.42}$$

which can be generalized for a multicompartmental model to

$$\mathrm{AUC} = \sum A_i/\lambda_i \tag{3.43}$$

Using Vd_{ss} and Cl_B, Equation 3.18 can again be used to calculate the overall T1/2 of drug in the body. This T1/2 reflects both distribution and elimination processes and is very useful as input into an interspecies allometric analysis. This is not equivalent to the terminal elimination half-life, T1/2 (λ_2), and must be calculated from the Cl_B and Vd_{ss} parameters.

Absorption in a Two-Compartment Model

When an extravascular dose is administered as input into a two-compartment model (Figure 3.13), the differential equation defining this model is

$$V_1 dC_1/dt = -(k_{12} + k_{10})C_1 V_1 + k_{21} C_2 V_2 + k_{01} X \tag{3.44}$$

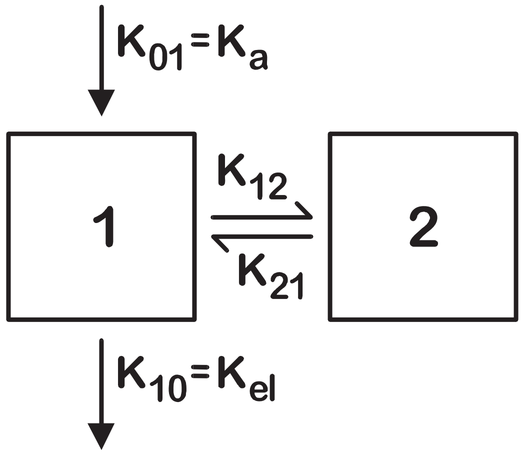

Figure 3.13 Generalized open two-compartment pharmacokinetic model with first-order absorption (K_{01}) into and elimination (K_{el}) from the central compartment. K_{12} and K_{21} represent intercompartmental constants reflecting distribution.

The movement of drug in the central compartment is now driven by three different concentrations: C_1, C_2 as well as the fraction of the administered dose D that is available for absorption (X). There are a number of approaches to solve this model. An example of the equation describing such a plasma profile would be

$$Cp = k_{01}D/V_1 \left[A_1' e^{-\lambda_1 t} + A_2' e^{-\lambda_2 t} - A_3' e^{-k_{01} t}\right] \tag{3.45}$$

In this case, the intercepts (A_n') are different than those obtained from an intravenous study (A_n) and significantly more complex since the "driving" concentrations in compartments one and two are now dependent upon the fraction absorbed in a fashion analogous to the terms of Equation 3.24 seen for absorption in a one-compartment model. However, in reality, it is difficult to separate k_{01} from λ_1 since the two are of a similar order of magnitude, coupled with the earlier discussed concern that early time points are often prone to large errors. Depending on the ratio of rate constants, the C-T profile may even appear monoexponential! The final complication is that absorption flip-flop may also occur making selection of k_{01} and λs very difficult. The only method to reliably address all of these problems is to conduct an independent intravenous bolus study using a two-compartment model and independently estimate λ_1 and λ_2 to arrive at an estimate of the absorbed dose. These equations are now easily analyzed using modern computer software.

Data Analysis and its Limitations

Clearly, as pharmacokinetic models become more complex, one must question the wisdom of pursuing such analyses. In reality, there are mathematical limitations to the complexity of the model able to be fit to an experimental data set which is based on the "information density," that is, how many data points are analyzed relative to how many parameters need to be calculated. This is similar to the statistical concept of "degrees of freedom." In practice, there are better approaches to model complex absorption using noncompartmental strategies of residence times and linear system deconvolution analysis, which are discussed in advanced texts. The final consideration with two-compartmental models, and one that is even more serious for multicompartmental models, is the actual structure of the model studied. Up until now, we have *assumed* that input into (absorption) and output from (elimination) the model are via the central compartment (model A), and furthermore, all samples are taken from this compartment and expressed as differential equations based on dC_1/dt. However, other possible structures exist for the basic two-compartment model. For example, drug may be infused into a tissue bed, or drug could distribute to the organ before metabolism and thus elimination in that organ. Many of these latter type of problems occur when the rate of distribution is actually slower than elimination making the initial exponential term reflect elimination. Very lipophilic chlorinated hydrocarbon chemicals may initially distribute extensively throughout the body and then slowly (periods of months) redistribute to the blood where metabolism would then occur. The redistribution rate constant would be the rate-limiting process. All would generate C-T profiles described by the sum of exponential very similar to those discussed above. However, the equations which *link* these fitted parameters to the underlying micro-rate constants would be very different.

Multicompartmental Models

The final level of compartmental model complexity to be dealt with in this chapter is the three-compartment model depicted in Figure 3.14 that generates the C-T profile in Figure 3.15. These data were obtained following intravenous gentamicin administration to dogs. In this case, gentamicin distributes into two different compartments from the central compartment, one with rates faster (k_{12}/k_{21}) and the other with rates slower (k_{13}/k_{31}) than k_{10}. The slopes of the C-T profile for λ_1 primarily reflects the contribution of rapid distribution while λ_3, the terminal slope, primarily reflects the contribution of slower distribution into the so-called deep compartment. This model is applicable to many three-compartment drugs encountered in veterinary medicine (e.g., aminoglycosides, tetracyclines, persistent chlorinated hydrocarbon pesticides). Drug elimination from the central compartment is primarily reflected in λ_2 or β and through general usage is termed the β *elimination phase*.

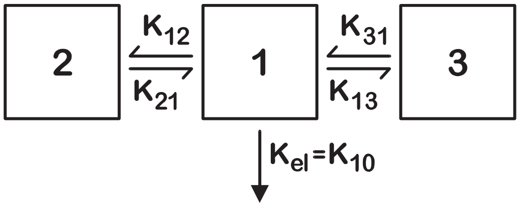

Figure 3.14 Three-compartment pharmacokinetic model after intravenous administration. Parameters are defined in the text.

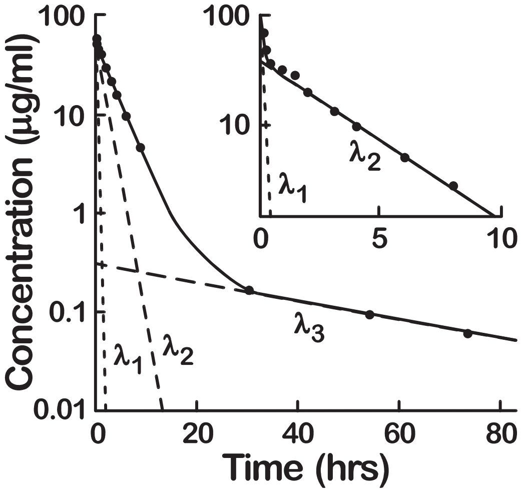

Figure 3.15 Semilogarithmic plot of plasma concentration versus time for intravenous gentamicin in the dog. Disposition is described by a three-compartment model when samples are collected over 80 hours and a two-compartment model when samples are collected for only 10 hours (insert).

These types of models are generally employed when experiments are conducted over long time frames and C-T profiles monitored to low concentrations. If the data are truncated at earlier times as shown in the insert of Figure 3.15, a normal two-compartment model is adequate to describe the data. However, if the goal of a study were to describe the tissue residue depletion profile of a drug in a food-producing animal, the tissue C_3-T profile would be of interest since it is the tissue where legal tolerances are established. This makes such complicated models useful in food animal veterinary medicine.

Models consisting of more than three compartments have been used when the data are of sufficient quality (sensitive analytical method, sufficient samples) to warrant such an analysis. The polyexponential equation describing n-compartment models (i = 1,2,3— n) is

$$C_p = \sum A_i\, e^{-\lambda_i t} \tag{3.46}$$

The differential equations needed to link these slopes and intercepts to the micro-rate constants are exceedingly complex and will not be discussed further. These complex models are only presented to give an appreciation of the types of models encountered when tissue residue predictions are encountered.

In respect to prediction of tissue residues, when a tissue sample is taken, one is not measuring just concentrations in that tissue since the vascular and extracellular fluid components of that tissue are actually part of the central compartment. Similar arguments can be made for other components. When one is looking at deep compartment disposition, this may be satisfactory since release from these depots are rate-limiting, making this tissue component larger than any other phase that has already reached equilibrium. Equations are available to fractionate a tissue mass into vascular, extracellular, and cellular components based again on Vd estimates. Alternatively, tissue cages or microdialysis probes may be inserted into the tissue mass and extracellular kinetics modeled. These data are often presented in veterinary studies dealing with antimicrobial distribution to infected tissues.

Compartmental modeling concepts and techniques have defined the discipline of pharmacokinetics and continue to be extremely useful tools. One- and two-compartment analyses form the basis for most models used in human as well as veterinary and comparative medicine. These two models also serve as the foundation upon which many of the other techniques now to be briefly discussed are based. Modern computers have facilitated the analysis of these data to the point that the user no longer has to derive all of the relevant differential equations. Comprehensive software packages are available to effortlessly perform these calculations, even if the data does not support the model analyzed! Concerns such as these have led many clinical pharmacologists in both human and veterinary medicine to move away from complex multicompartmental models and adopt so-called *model-independent* approaches when their goal is to predict dosage regimens for clinical applications.

Noncompartmental Models

Over the last two decades, there has been generalized adoption of noncompartmental methods in veterinary and comparative pharmacokinetics. Noncompartmental models were first developed and applied to radiation decay analysis and remain dominant in the physical and biological science literature for general applications. Since their first application to problems in pharmacokinetics by Yamaoka in 1979, noncompartmental methods have grown steadily in use. This approach is for the most part actually an application of well-developed statistical moment theory, a full discussion of which is beyond the scope of this text. The approach involves primarily calculation of the Slopes, Heights, Areas and Moments (SHAM) of plasma concentration time curves. Statistical moment theory describes drug behavior based on the mean or average time an administered drug molecule spends in a kinetically homogeneous space, a concept identical to that of a compartment. The difference again is that no specific inferences are being made about the structure of these spaces.

Rather than being based on diffusion, these models are based on *probability density functions* that define drug disposition in terms of the probability of the drug being in a specific location. Instead of determining rates in terms of rate constants or half-lives, they describe processes in terms of statistical moments; the most useful is the mean residence time (MRT; τ). These are based on plasma concentration data and are determined by calculating areas under concentration versus time curves. MRT is calculated as

$$MRT = \frac{\int_0^\infty t\,C\,(t)\,dt}{\int_0^\infty C\,(t)\,dt} = \frac{AUMC}{AUC} \tag{3.47}$$

The denominator of this equation is the AUC we have discussed earlier in terms of calculating clearance and bioavailability. The numerator is known as the area under the [first] moment curve (AUMC), which is the CT-T profile. AUC and AUMC are depicted in Figure 3.16.

The MRT could be thought of as the statistical moment analogy to the half-life (T1/2), and it is inversely related to the first-order elimination rate of a one-compartment open model:

$$MRT_{TV} = 1/K_{el} \tag{3.48}$$

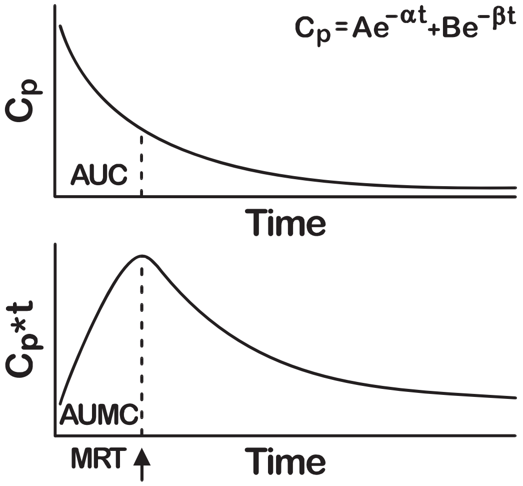

Figure 3.16 Plasma concentration versus time (C-T) and its first-moment (CT-T) plots demonstrating AUC, AUMC, and MRT.

Rearranging demonstrates that $K_{el} = 1 / MRT_{iv}$. Recalling Equation 3.18 where T1/2 = 0.693/K_{el}, substitution gives us

$$T1/2 = 0.693\ (MRT) \tag{3.49}$$

The MRT thus becomes an excellent parameter to describe the length of drug persistence in the body, much as the half-life is used in many compartmental pharmacokinetic models. The T1/2 used in this context is the elimination T1/2 in the body, and not that calculated from the terminal exponential phase for multicompartmental models. If the dose of drug is administered by intravenous infusion, the MRT_{iv} may be calculated as

$$MRT_{iv} = MRT_{infusion} - (Infusion\ Time)/2 \tag{3.50}$$

where $MRT_{infusion}$ is simply calculated from the observed data using Equation 3.47.

The primary task to solve model–independent or noncompartmental models is the direct estimation of the moments from data. This essentially is determining the relevant AUCs and moments from the C-T profile. When the C-T profile is described by a polyexponential equation of the form $f(t) = A_i e^{-\lambda it}$, Equation 3.43 ($AUC = \Sigma A_i / \lambda_i$) can be generally used to determine AUC. The AUMC may then be calculated as

$$AUMC = \sum A_i/\lambda_i^2 \tag{3.51}$$

The simplest and most commonly used method for estimating area under any curve is the trapezoidal rule. This technique is important since it is the primary method used to assess bioavailability by regulatory agencies. The approach is again illustrated in Figure 3.17.

$$AUC = \sum_{n=1}^{N} \frac{C_n + C_{n+1}}{2}(t_{n+1} - t_n) \tag{3.52}$$

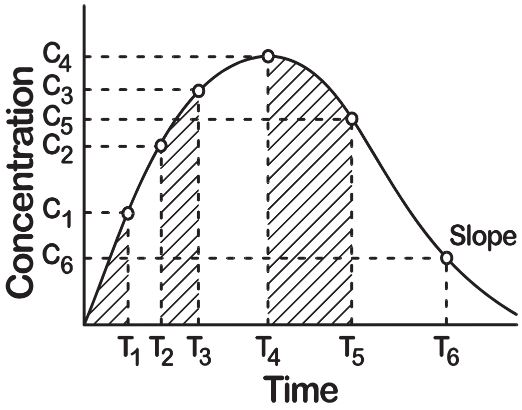

Figure 3.17 Breakdown of a plasma concentration versus time curve into trapezoids used to calculate the area under the curve. The terminal area from T_6 to T_∞ is calculated from extrapolating the terminal slope.

The summation is over N trapezoids, formed by N+1 data points. This algorithm is quick and, if enough data points are available, relatively accurate. It is also a simple algorithm to implement on a computer. The area under each pair of connected points describes a trapezoid (except when one of the points has zero value, in which case one of the legs of the trapezoid has zero length, making a triangle). The area under the entire curve is then the sum of the areas of the individual trapezoids, which can easily be calculated. The area under the final triangle is estimated by the AUC and must be estimated to infinite time. Generally, this portion of the AUC should be less than 20% of the total. Many methods have been proposed for this, the most common being $AUC_{T\to\infty} = C_T / \lambda_n$, where λ_n is the terminal slope of the C-T profile. The estimation of the first moment for calculation of MRT is the summed trapezoids plotted on a CT-T graph. The attraction of statistical moment analysis to pharmacokinetics is the use of trapezoids to determine the relevant areas. No assumptions but the underlying mechanisms of drug disposition are made, and computer curve fitting is not required.

To complete this brief introduction to this topic that is the basis of many commercial software packages, one other residence time having general application in clinical pharmacology is the mean absorption time (MAT). Other residence times may be calculated but are not used in determining dosage regimens in clinical medicine. MAT is technically the mean arrival time into the systemic circulation of bioavailable absorbed molecules. MAT is the statistical moment theory equivalent of estimating K_a. MAT is a computationally straightforward method to characterize the rate of drug absorption in bioavailability studies. The simplicity of this approach is that transit times are additive. MAT is the mean time for drug molecules to remain unabsorbed. MAT is simply the difference in MRT following intravenous injection (MRT_{IV}) and another noninstantaneous administration (MRT_{Route}):

$$MAT = MRT_{Route} - MRT_{IV} \tag{3.53}$$

Assuming absorption is described by a first-order process with an apparent rate constant of k_a, then

$$MAT = k_a^{-1} \tag{3.54}$$

making the absorption half-life

$$T1/2_{[abs]} = \ln 2 \cdot MAT \tag{3.55}$$

On the other hand, when absorption is assumed to be a zero-order process (e.g., constant rate), then

$$MAT = T/2 \tag{3.56}$$

where T is the duration of the absorption. Note the similarity to the infusion Equation 3.50 above. In reality, a constant rate infusion is a zero-order absorption whose MAT is just one-half the length of the infusion.

The reader should recall that the determination of systemic availability expressed in Equation 2.4 [$F = (AUC_{Route})(Dose_{IV})/(AUC_{IV})(Dose_{Route})$] is a noncompartmental analysis. An AUC should be determined by the trapezoidal methods presented in this chapter. If the point of an analysis is to determine bioequivalence between two formulations, one is actually calculating relative systemic availability, a concept equivalent to determining whether two formulations are clinically interchangeable. In addition, the metrics time to peak concentration (T^{max}) and peak concentration (C^{max}) are often compared. Comparison of MATs would also shed light on the equivalence of two formulations. The reader should consult the references in the section "Selected Readings," later in this chapter for further approaches and the Food and Drug Administration website (www.fda.gov/CVM) for current bioequivalence guidelines for veterinary products.

The determination of Cl_B using statistical moment theory is easily obtained using the previously defined Equation 3.16 where $Cl_B = D/AUC$. Using the trapezoidal methods to estimate AUC makes this a robust estimate of clearance. The volume of distribution at steady-state (Vd_{ss}), according to statistical moment theory, is simply the product of MRT and CL:

$$Vd_{SS} = Cl_B\ MRT \tag{3.57}$$

This, incidentally, affords the expression for half-life as a function of clearance, by solving Equation 3.57 for MRT:

$$T_{1/2} = \frac{\ln 2 \cdot Vd_{SS}}{Cl_B} \tag{3.58}$$

which is the same as that presented in Equation 3.18. Substitution of the respective expressions for MRT (Equation 3.47) and CL (Equation 3.16) into Equation 3.57 yields

$$Vd_{SS} = \frac{D_{i.v.} \cdot AUMC}{AUC^2} \tag{3.59}$$

Another volume parameter also calculated using statistical moments sometimes encountered for dosage regimens is Vd_{area}:

$$Vd_{area} = \frac{D_{i.v.}}{k_{el} \cdot AUC} \tag{3.60}$$

Statistical moment methods provides a powerful tool for calculating many of the common pharmacokinetic parameters that are routinely encountered in veterinary medicine. This includes the concept of bioequivalance discussed above, as well as generating parameters that are used to construct dosage regimens and assess the effect of disease on drug effects. As can now be even more fully appreciated, Cl_B and Vd_{ss} are truly independent parameters that quantitate distribution and excretion using computationally robust techniques based on minimal model-specific assumptions. We have presented this approach since it is the primary method by which pharmacokinetic parameters are now determined in veterinary medicine. Table 3.2 is a compilation of equations useful to calculate these parameters from an analysis of a C-T profile.

Table 3.2 Noncompartmental equations for calculating common pharmacokinetic parameters

$Cl_B = Dose / AUC$
$Cl_D = V_c\ \lambda_1 - Cl_B$
$Vd_{ss} = (Dose \times AUMC) / AUC^2$
$V_c = Dose / Cp_0$
$MRT_{iv} = AUMC/AUC = V_d(ss) / Cl_B$
$MAT = MRT_{route} - MRT_{iv}$
$T1/2 = 0.693\ MRT = 0.693\ Cl_B / Vd_{ss}$
$T1/2\ (\lambda) = 0.693 / \lambda$
$F = (AUC_{route})\ (Dose_{iv}) / (AUC_{iv})\ (Dose_{route})$
$AUC = \Sigma\ A_i / \lambda_i$
$AUMC = \Sigma\ A_i / (\lambda_I)^2$

Note that AUC and AUMC could be calculated using trapezoidal analysis of areas rather than fitting curves to obtain estimates of A_i and λ_i.

Nonlinear Models

Most pharmacokinetic models incorporate the common assumption that drug elimination from the body is a first-order process, and the rate constant for elimination is assumed to be a true constant, independent of drug concentration. In such cases, the amount of drug cleared from the body per unit time is directly dose or concentration dependent, the percentage of body drug load that is cleared per unit time is constant, and the drug has a single constant elimination half-life. Fortunately, first-order elimination (at least apparent first-order elimination) is typical in drug studies. First-order linear systems application greatly simplifies dosage design, bioavailability assessment, dose–response relationships, prediction of drug distribution and disposition, and virtually all quantitative aspects of pharmacokinetic simulation.

However, drugs most often are *not* eliminated from the body by mechanisms that are truly first-order by nature. Actual first-order elimination across all concentrations applies only to compounds that are eliminated exclusively by mechanisms not involving enzymatic or active transport processes (i.e., processes involving energy). As presented in Chapter 2, they are primarily driven by diffusion and obey Fick's Law. The subset of drugs not requiring a transfer of energy in their elimination is restricted to those that are cleared from the body by urinary and biliary excretion and, among those, only drugs that enter the renal tubules by glomerular filtration or passive tubular diffusion. All other important elimination processes require some form of energy-consumptive metabolic activity or transport mechanism. What is the impact of this on pharmacokinetic parameters?

The reason energy-involved processes are not strictly first-order is that they are generally *saturable,* or more specifically are *capacity-limited.* At clinical dosages, the majority of drugs do not reach saturation concentrations at the reaction sites, and follow first-order linear kinetics. Recalling for first-order processes, a constant percentage of remaining drug is cleared per unit time, and the drug has a discrete, concentration-independent elimination rate constant (K) and thus half-life. For drugs eliminated by zero-order kinetics or saturated pathways, however, a constant quantity of drug is eliminated per unit of time, and this quantity is drug concentration independent and the drug does not have a constant, characteristic elimination half-life. The potential impact of saturable, leading to zero-order (versus first-order) elimination, can be profound, and its effects include altered drug concentration profiles, scope and duration of drug activity, and distribution and disposition among tissues. Saturable hepatic metabolism may markedly affect drug absorption due to reduced clearance (lower hepatic extraction) and altered first-pass activity after oral administration. Nonlinearity is associated with a nonconstant T1/2 at different doses or when a plot of dose versus AUC is not linear, indicating that Cl is reduced as dose increases.

The primary technique used to model saturable metabolic process employs the Michaelis–Menten rate law. This can be expressed as

$$dC/dt = -(V_{\max})(C)/(K_m + C) \tag{3.61}$$

where V_{max} is the maximum velocity (rate) of the reaction, and K_m is the Michaelis constant that relates concentration to effect. There are two notable simplifying conditions of the Michaelis–Menten equation. If $K_m \gg C$, then Equation 3.61 reduces to

$$dC/dt = -(V_{\max})(C)/(K_m) \tag{3.62}$$

This is equivalent to first-order elimination after IV administration in a one-compartment model where $dC/dt = -K_{el}C$. Thus, assuming elimination by a single biotransformation process, the first-order elimination rate constant K_{el} becomes V_{max}/K_m. If however, $K_m \gg C$, saturation is occurring and then Equation 3.62 collapses to

$$dC/dt = -V_{\max} = -K_0 \tag{3.63}$$

The rate in this case is independent of drug concentration (i.e., a constant), which describes a zero-order process, and the rate of drug elimination is now equal to $-K_0$.

Often, drugs are found to be eliminated by both first-order and nonlinear processes in parallel. In such cases, Equation 3.62 must be expanded to include the strictly first-order elimination processes:

$$\frac{dC}{dt} = -\frac{V_{\max}C}{K_m + C} - k'_{el}C \tag{3.64}$$

What is the impact of this on clinical veterinary pharmacology? The precise calculation of V_{max} and K_m is not done in clinical practice. However, values of Cl_B and T1/2 are assumed to be constant. When saturation occurs, Cl_B decreases and T1/2 increases, resulting in dosage regimens that accumulate with potential adverse effects. Recalling discussions in Chapter 2 on metabolism and saturation, the same phenomenon can also occur if enzyme inhibition occurs. In contrast, enzyme induction would increase clearance and reduce T1/2 resulting in decreased and potentially ineffective plasma concentrations.

Summary of Modeling Approaches

With the advent of modern computers, advanced software packages and sensitive and high-throughput analytical techniques, more comparative pharmacokinetic data are becoming available, and such data are being included in package inserts of approved products. The focus of this chapter is to develop basic pharmacokinetic concepts that serve as the foundation of dosage regimen construction in clinical practice. Obviously, many of the more complex models were only presented in order to illustrate these basic concepts. It is crucial that the practitioner know assumptions and limitations involved in a specific clinical case. However, there are additional pharmacokinetic approaches that are used in comparative medicine which in some cases complement the basic approaches above, and in others offer significant advantages. Two of these will be briefly introduced. Standard pharmacokinetic textbooks should be consulted for more detail.

Population Pharmacokinetics

All of the models discussed to this point have been focused on predicting drug concentrations in the individual animal. However, in many cases populations are of interest. For example in dogs, it would be ideal to know the basic pharmacokinetic parameters for a drug in the population at large that would apply to all breeds, ages, and gender. More important would be knowledge of which subpopulation had significantly different parameters. This is normally achieved by collecting a large number of plasma samples in individual animals and averaging resulting pharmacokinetic data from small (4–6 animals) studies. Recently, techniques have been developed that allow one to conduct studies in large numbers of individuals with less individual sampling. The approach uses very simple pharmacokinetic models (e.g., Equation 3.13) or SHAM approaches, and collect more physiological data (body weight, age, creatinine) to solve the models. For example, instead of estimating Cl_B only from C-T data, one establishes a relation between GFR and Cl_B, and through statistical approaches, uses both data sets. The mathematics and statistical approaches in these so-called "mixed-effect" models (called *mixed* because kinetic and statistical models are combined) are beyond the scope of the present text. However, their adoption by scientists in drug development areas coupled with commercial software platforms that facilitates their use will ensure that better estimates of pharmacokinetic parameters, applicable to populations, will be available.

This is especially important in veterinary medicine where breed and species differences are extreme and data quantitating these differences are scarce. Recently, many additional so-called population pharmacokinetic studies have been conducted in veterinary medicine as a tool to combine pharmacokinetic data across different studies when specific endpoints are desired. They are not used in the same manner as they are in large, well-funded phased human clinical trials; however, they provide a tool for combining datasets across disparate published studies and smaller clinical trials. For example, data from field studies have been combined with regulatory datasets to predict tissue withdrawal times after drugs such as flunixin have been administered to disease animals requiring a prolonged withdrawal time before slaughter (see Wu et al., 2013; Li et al., 2014).

Physiological-Based Pharmacokinetic (PBPK) Modeling

The second approach to studying pharmacokinetics in animals and humans is PBPK modeling. This approach is fundamentally different than discussed above as models are constructed by defining the body as a series of anatomical organs and tissues connected by the vascular system (Figure 3.18). Data is collected in plasma as well as tissue compartments, which are defined both on the basis of overall effect on drug disposition as well as sites of action or toxicity. Data input consists of blood flows into tissues as well as the partitioning coefficients for drug between blood and tissues. The model is solved in terms of a series of mass-balance equations defining input and output from each organ, very similar to that discussed when clearance was introduced in the last chapter (Equation 2.6). Advanced software packages facilitate solving these complex equations.

These models are extensively employed in the field of toxicology where data collected in laboratory animals are used to extrapolate to humans. In these cases, models may be defined in mice or rats, and then human physiological parameters inputted to estimate human disposition. The models are well suited to integrate in vitro laboratory data on toxicity or effect, as well as being able to simultaneously model parent drug and metabolite disposition. They would be ideal to model the so-called pharmacodynamic effect compartment introduced in Chapter 4. They have recently been used to study tissue residue depletion in food animals because they allow for predictions in the target tissues monitored by veterinary regulatory authorities. Similar to the ability of population models to analyze data across diverse sets of data, PBPK models can do the same in addition to detailing more physiologically realistic absorption models and incorporating in vitro data (see recent examples by Leavens et al., 2014; Lin et al., 2015). A comprehensive review detailing how PBPK models work and applications to veterinary medicine has recently been published (Lin et al., 2016).

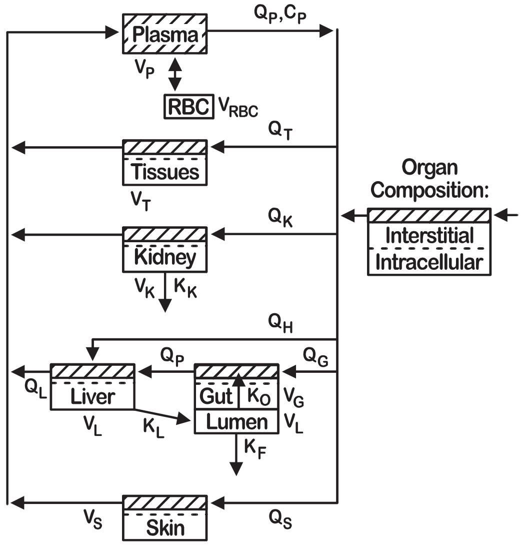

Figure 3.18 Structure of a physiologically based pharmacokinetic model (PBPK) incorporating disposition in plasma, liver, kidney, skin, and the gastrointestinal tract. Elimination from the body occurs from the kidney (K_K), liver (K_L), and gut lumen in feces (K_F). Oral absorption is allowed (K_O). V refers to organ volumes of distribution and Q to organ blood flows.

Dosage Regimens

The primary use of pharmacokinetics in a clinical setting is to calculate safe and effective drug dosage regimens for patients. These are generally based on target plasma drug concentrations that are believed to be therapeutically effective. The dose required to achieve and then maintain these target concentrations must be calculated using a knowledge of the drug's pharmacokinetic parameters in these individuals.

This concept is best addressed by visualizing the drug's C-T profile after multiple dose administration as depicted in Figure 3.19. There are two descriptors of the dosage regimen that are important to describe a

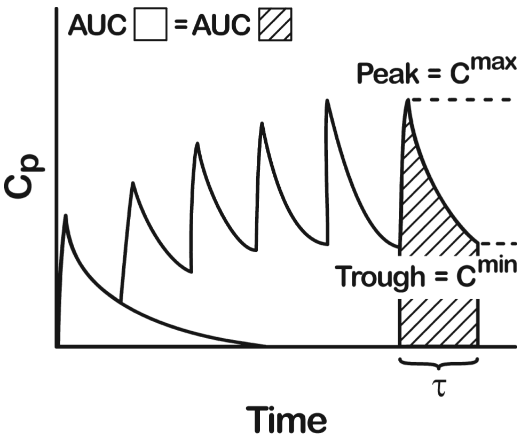

Figure 3.19 Plasma concentration (Cp) versus time profile after multiple extravascular drug administration demonstrating accumulation. Peak and trough concentrations represent those after achievement of steady-state where the AUC under a dosing interval τ (hatched area) is equal to that after a single dose (unshaded area).

multiple dose regimen. These are the dose and dosage interval (τ). The dose is further classified as the initial or *loading dose* (D_L) required to rapidly achieve an effective plasma concentration and the *maintenance dose* (D_M) needed to sustain these concentrations. The resulting profile is characterized by *peak* (C^{max}) and *trough* (C^{min}) plasma concentrations, which result after the animal has achieved a steady-state condition.

The shape of such a multiple dosage regimen is dependent upon the relationship between the T1/2 of the drug and the length of the dosage interval, τ. Assuming that a single dose of drug is administered to an animal, the resulting C-T profile after extravascular administration will resemble that depicted in Figure 3.7 (plotted on a semilog C-T axis), which (plotted on a normal C-T axis) is the left-most profile in Figures 3.19 and 3.20. The AUC of this C-T segment describes the quantity of drug cleared from the body (Equation 3.16). If a second dose of drug were given after the first dose were completely eliminated (e.g., approximately five T1/2s), then this profile would be repeated as depicted in Figure 3.20. This dosage regimen, where τ is ≫ 5 T1/2s, does not result in any drug accumulation in the body. The peak and trough plasma concentrations of this multiple dose regimen is the same as seen after a single dose and the equations presented earlier (Equation 3.13 for an intravenous dose and Equation 3.24 for an extravascular dose) may be used to describe the profile. The dose required to achieve a specific peak concentration or C^{max} after administering a very rapidly absorbed preparation is essentially obtained by rearranging the equation for volume of distribution (Equation 3.12) which becomes

$$Dose = (C^{\max})\, Vd \tag{3.65}$$

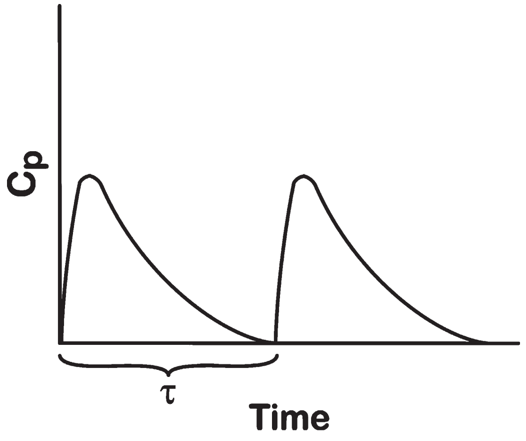

Figure 3.20 Plasma concentration (Cp) versus time profile after multiple extravascular drug administration with no accumulation, resulting in independent pharmacokinetics described by two single-dose profiles.

If the drug is not completely bioavailable (e.g., $F < 1$), this equation is divided by the systemic availability F. Administering this dose at every τ will result in the same C-T profile characterized by C^{max} and a C^{min} of essentially zero.

However, the more likely scenario is that depicted in Figure 3.19 where a second dose is administered before the first dose is completely eliminated from the body. In this case, the drug concentrations will accumulate with continued dosing. This accumulation will stop or reach a *steady-state* when the amount of drug administered at the start of each dosing interval is equal to the amount eliminated during that interval. This can be appreciated since the AUC under one dosing interval is equal to that after a single dose administration. In fact, steady-state could be defined as the dosing interval where the AUC for that interval is equal to the single dose AUC. Administering repeated doses at a τ defined in this manner will continuously produce a C-T profile with the same peak and trough plasma concentrations.

There are a series of simple formulae derived from basic pharmacokinetic principles that can be used to precisely derive these profiles. The first is to determine C^{avg}, which is a function of the Vd and the ratio of the T1/2 and τ where

$$C^{avg} = \frac{(1.44)(F)(D)}{Vd_{area}} \bullet \frac{T1/2}{\tau} = \frac{C^{\max} - C^{\min}}{\ln(C^{\max}/C^{\min})} \tag{3.66}$$

Recalling the relationship between T1/2, Cl and Vd presented earlier in Equation 3.18, rearrangement yields $1/Cl = 1.44\ T1/2/Vd_{area}$. It is instructive when studying these relations to recall that 0.693 is the ln 2 and 1.44 is 1/ln2. Substituting this into Equation 3.66 yields

$$C^{avg} = (F/Cl)\ (D/\tau) \tag{3.67}$$

Another relationship becomes evident from these formulae. We learned earlier that Cl is defined as D/AUC, which allows Equation 3.67 to be algebraically expressed as $C^{avg} = (F)\ (AUC)/\tau$. This relation quantitates the observation presented earlier that the AUC under any dosing interval τ will always be the same when steady-state conditions are achieved.

Two factors that are important in designing dosage regimens emerge from Equations 3.66 and 3.67. The ratio D/τ can be defined as the *dosage rate* and is the major determinant under the control of the clinician that determines the amount of drug which will accumulate in the body. The ratio $T1/2/\tau$ is a proportion relating the relative length of the dosing interval to the half-life of the drug. If the inverse of this ratio is taken, the *relative dosage interval* ε may be defined as: $\varepsilon = \tau/T1/2$. These two ratios provide useful parameters to gauge the shape and height of the C-T profile produced by a tailored dosage regimen, as well as adjust dosages in disease states with reduced clearances.

The primary factor governing the extent of drug accumulation in a multiple dose regimen is the fraction of a dose eliminated in one dosing interval, termed f_{el}. This can be easily calculated by first determining the amount of drug remaining at the end of a dosing interval, f_r. We showed earlier that the amount of drug in the body at any time t is given by the exponential (Equation 3.6) relation $X_t = X_0\ e^{-kt}$. If one substitutes τ for t at the end of a dosing interval, then f_r is defined as

$$f_r = 1 - f_{el} = X_t/X_0 = e^{-k\tau} = e^{-\lambda\tau} \tag{3.68}$$

where k is the fractional elimination constant or the relevant slope of the terminal phase of the C-T profile governing the disposition of the drug. It can be rearranged to

$$f_{el} = 1 - e^{-0.693(\tau/T1/2)} = 1 - e^{-0.693\ \varepsilon} \tag{3.69}$$

Using f_{el}, the peak and trough concentrations may be calculated as

$$C^{max} \frac{(F)\ (D)}{(Vd_{area})\ (f_{el})} \tag{3.70}$$

$$C^{min} = (C^{max})\ (1 - f_{el}) \tag{3.71}$$

The ratio of the fluctuation in $C_p{}^{max}$ and $C_p{}^{min}$ can be determined as

$$C^{max}/C^{min} = e^{0.693(\tau/T1/2)} = e^{0.693\ \varepsilon} \tag{3.72}$$

and further,

$$\ln\ (C^{max}/C^{min}) = 0.693(\tau/T1/2) = 0.693\ \varepsilon \tag{3.73}$$

This is an extremely powerful relationship that demonstrates that the magnitude of fluctuations in a C-T profile is directly related to the *relative* dosage interval ε. As either τ increases or $T1/2$ decreases, this ratio will get larger and result in a greater fluctuation in drug concentrations.

Using these relationships and rearranging Equation 3.70 to solve for dose, one can now derive the dosage formulae required to achieve a C-T profile with specified target peak and trough concentrations:

$$\begin{aligned} D_M &= (f_{el})\ (Vd_{area})\ (C^{max})/F \\ &= Vd_{area}(C^{max} - C^{min})/F \end{aligned} \tag{3.74}$$

$$\begin{aligned} D_L &= (D_M)\ (f_{el}) \\ &= (Vd_{area})\ (C^{max})/F \end{aligned} \tag{3.75}$$

Thus to construct a dosage regimen, the only parameters that are required are the Vd_{area} and $T1/2$ (and hence λ or k_{el}) of the drug to calculate f_{el}. If one is targeting only the average plasma concentration, then Equation 3.66 can be solved for dose as

$$\begin{aligned} D_M = \frac{(C^{avg})(Vd_{area})}{(1.44)(F)} \times \frac{\tau}{T1/2} \times \frac{(0.693)\ (C^{avg})\ (Vd_{area})}{F} \\ \times \frac{\tau}{T1/2} \times \frac{(C^{avg})(Cl)(\tau)}{F} \end{aligned} \tag{3.76}$$

The magnitude of f_{el} is a good estimate of the degree of fluctuation that occurs between the peak and trough concentration at steady-state. As the ratio of $\tau/T1/2$ or ε approaches zero, f_{el} approaches zero and the amount of fluctuation in a dosage interval is minimal. In contrast, when this ratio is large, f_{el} approaches one and the peak and trough concentrations have a large degree of fluctuation.

When f_{el} is very small, C^{max} approaches C^{min} since f_{el} approaches zero when τ approaches zero. The resulting C-T profile becomes characterized by C^{avg}. This occurs when the drug is given as an intravenous infusion. The rate of an intravenous infusion (R mg/min) is essentially an *instantaneous* dose rate and is equivalent to D/τ. When R is inserted in Equation 3.67 for D/τ and F is set equal to 1 (since an intravenous dose is be definition 100% systemically available),

$$C^{avg} = R/Cl \tag{3.77}$$

and

$$R\ (mg/min) = (C^{avg})\ (Cl) \tag{3.78}$$

which is identical to Equation 3.20 presented earlier for the steady-state plasma concentration (C^{ss}) obtained after administering an intravenous infusion. If one desires that concentration be achieved immediately, then a loading dose may be calculated as

$$D_L = (C^{avg})\ (Vd) \tag{3.79}$$

Comparing Equations 3.66 and 3.77 is instructive since it demonstrates the dependence of the average steady-state concentration on the rate of drug input (R or D/τ) in mass/time and the rate of drug elimination exemplified by the clearance. When constructing and comparing dosage regimens, the C^{avg} of any two regimens will always be the same as long as D/τ is constant. This factor becomes very important when dosage regimens are constructed for patients with impaired clearance due to renal disease. The larger the f_{el} or ε is in a single dosage interval τ, the greater the fluctuation in plasma concentrations. To minimize fluctuation but maintain a constant C^{avg}, smaller maintenance doses (D_M) must be administered at shorter dosage intervals.

It is also important to stress at this point that the length of time required to achieve steady-state for any dosage regimen is solely based on the rate-controlling λ or T1/2 of the drug in the clinical situation. Thus with drugs having a prolonged half-life, a loading dose may often have to be administered to rapidly achieve therapeutically effective plasma concentrations.

The principles presented in this chapter may be widely applied for a number of therapeutic situations. For most drugs employed in a clinical setting, the relevant T1/2 will be that governing the elimination of the drug's C-T profile. If the drug exhibits nonlinear pharmacokinetic properties and accumulates, saturation may occur and the clearance operative at low concentrations may be reduced at the higher concentrations seen at steady-state, leading to further accumulation and potential toxicity. In contrast, if the drug induces its own metabolism, the disposition and thus required dosage regimen may be greater after chronic use to prevent relapse. This has been seen with certain anticonvulsant drugs.

Other considerations are operative when administering extravascular drugs with relatively slow rates of absorption. In many cases, the governing rate process may be the absorption phase (k_a) and a flip-flop situation will occur. In this case, it will take five *absorption* T1/2s to reach steady-state. These approaches to constructing dosage regimens are ideally suited when pharmacokinetic parameters are obtained from the noncompartmental models. In these cases, the same equations may be used.

Comments on Efficacy and Safety

The final point to consider is the relationship between the target C^{max} and C^{min} concentrations and therapeutic or toxic effect. This relation is best presented in Figure 3.21, which depicts a hypothetical C-T profile versus various target Cs for efficacy and toxicity. The precise manner by which a pharmacokinetic profile is linked to its pharmacodynamic or toxicodynamic effects will be presented in Chapter 4. This relationship is very dependent upon the pharmacology of the drug itself, and cannot be easily generalized across all drugs. As will be discussed in the next chapter, drug potency, efficacy, sensitivity, and specificity define the mathematical nature of the link between the C-T profile and effect. Individual chapters of this text must be consulted for an overview of mechanism of drug action, that is, what biochemical receptors are targeted by the individual drug. If an antimicrobial is involved, the mechanism of bacteria killing is important.

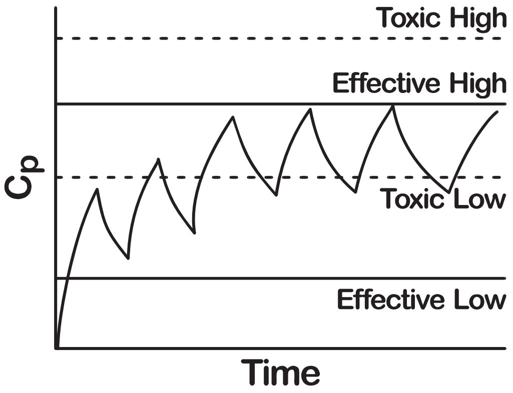

Figure 3.21 Relationship between a multiple-dose plasma concentration versus time profile and thresholds for efficacy and toxicity, which define the therapeutic benefit/risk ratio for the drug.

It is instructive to realize that the form of a C-T profile is by itself only dependent upon the dosage regimen parameters (D/τ) and the pharmacokinetics of the drug in the patient. The resulting efficacy or toxicity of the profile is dependent upon the underlying pharmacology and toxicology of the drug. These biological effects are often, though not always, correlated to plasma concentrations. Thus, for a specific drug, one might have data that would indicate that efficacy would occur when C is maintained above the *effective low* concentration and toxicity would be expected to occur only if concentration exceeded the *toxic high* level plotted. In this case, the dosage regimen that produced this C-T profile would be considered optimal since at steady-state it is well within the *therapeutic window* defined by these two thresholds. However, if the efficacy of the drug were defined by the *effective high* threshold plotted, the regimen would not be therapeutically effective. Similarly, if the relevant toxicological threshold were the *toxic low* line in this figure, one would predict that this regimen would be unsafe to administer.

Adjusting for Disease

One of the primary and most common factors that affects the disposition of a drug in the body is disease-induced changes in renal function. It is no surprise that renal disease has a profound impact on the disposition of a drug in the clinical setting. Many drugs are excreted primarily in urine as unchanged pharmacologically active drug. Drugs excreted in this manner accumulate in the body during renal insufficiency as a direct result of decreased renal clearance and is the primary manifestation of renal disease, which is compensated for in clinical dosage adjustment regimens. Renal disease can also influence other aspects of drug disposition, including altered protein binding, volume of distribution, and hepatic biotransformation. All of these effects complicate the establishment of safe and efficacious regimens for drug therapy. The chapters on specific drugs should be consulted when considering their use in such patients.

Of course, the obvious choice for selecting a drug for a patient with renal disease is to use a drug not cleared by the kidney. If this is not possible, current approaches for constructing adjusted dosage regimens for renal insufficiency or failure compensate only for decreased renal clearance of the parent drug and are based upon the principles of dosage regimen construction discussed above. In this approach, we assume (1) a standard loading dose is administered; (2) drug absorption, volume of distribution, protein binding, nonrenal elimination, and tissue sensitivity (dose–response relation) are unchanged; (3) creatinine clearance is directly correlated to drug clearance; and (4) there is a relatively constant renal function over time.

The ultimate aim of dosage adjustment in renal disease is to fulfill the fundamental therapeutic postulate that the C-T profile should be as similar as possible to the normal situation. Recall above that ε, the ratio τ/T1/2, determines the fluctuation in a multiple dose C-T profile based on its influence on the value of f_{el} from Equation 3.69. The dose ratio, D/τ, determines the average steady-state plasma concentration (C^{avg}). If τ is not adjusted in the face of an increasing T1/2 in a patient with renal failure, C^{avg} will dramatically increase, as can be seen from revisiting Equation 3.66. This can be compensated either by reducing D or increasing τ in this equation, which is the basis of the dose modification methods introduced below. However, the fluctuations in these regimens is a function of f_{el} which in a renal disease patient is dependent upon ε. Thus τ must be increased to compensate for the prolonged T1/2 if f_{el} and thus fluctuations are to be dampened. When constructing dosage regimens for patients in renal disease that has fundamentally altered pharmacokinetic parameters, both D and τ must be modified to achieve C^{avg} and f_{el}, which are similar to the patient with normal renal function.

Let us assume that one has already defined a safe and effective dosage regimen for use in a normal patient. These normal dosage regimens are then adjusted according to the dose fraction by two basic procedures. The first method, termed *constant-interval, dose-reduction* (DR), reduces the dose (D) by a factor of the dose fraction. Dose interval (τ) is the same as that used in the healthy animal. The dose fraction K_f is calculated as the ratio of diseased/healthy drug Cl, GFR or creatinine clearance.

$$\begin{aligned} D_{renal\ failure} &= D_{normal}\,K_f \\ \tau_{renal\ failure} &= \tau_{normal} \end{aligned} \tag{3.80}$$

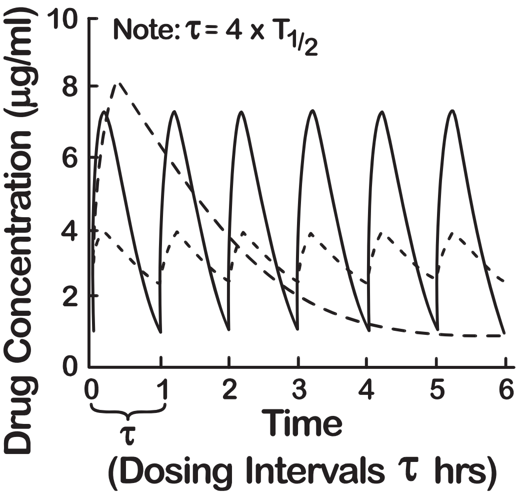

Figure 3.22 Comparison of constant dose (–––) and constant interval (----) regimens in renal failure (Cl_{cr} = one-sixth usual) with a normal dosage regimen (——) in a healthy patient. τ is the dosage interval.

The second method, *constant-dose, interval-extension method* (IE), extends the dosage interval by the inverse of the dose fraction, a value referred to as the *dose-interval multiplier:*

$$\begin{aligned} \tau_{renal\ failure} &= \tau_{normal}(1/K_f) \\ D_{renal\ failure} &= D_{normal} \end{aligned} \tag{3.81}$$

This type of dose adjustment strategy may also be implemented through the use of a nomogram where the dosage interval multiplier for this IE regimen is simply read off a plot of creatinine clearance. A comparison of these two methods is presented in Figure 3.22.

The therapeutic goal is to maintain a constant product of (T1/2 × D/τ) in healthy animals and those with renal failure. When this product is constant, the average steady-state plasma concentration of drug will remain unchanged. This is the approach followed in the DR and IE methods. A constant steady-state plasma concentration is achieved by the use of the dose fraction to compensate for decreased T1/2 in the following manner:

$$(T1/2\,D/\tau)_{normal} = K_f(T1/2\,D/\tau)_{renal\ failure} \tag{3.82}$$

When repeated doses of a drug are administered, accumulation occurs until steady-state plasma concentrations are achieved, a process taking five half-lives. The prolonged T1/2 present in patients with renal insufficiency would cause excessive delay in attaining steady-state concentration. Therefore, an appropriate loading dose should always be administered so that a therapeutic concentration of the drug is immediately attained. If the constant interval method is employed, this can be accomplished by giving the usual dose initially, followed by the calculated reduced dose. If the constant dose method is used, the initial two doses should be given according to the usual interval. The selection of which method to use is very drug dependent, both in terms of efficacy and potential toxicity.

The above equations hold for drugs that are excreted solely by the kidney, since the dose fraction adjusts dosages as if only renal elimination occurred. For drugs undergoing biotransformation, an estimate of the percent of nonrenal clearance is necessary. More detailed texts should be consulted for dealing with these cases. If hepatic disease is present, the same strategy holds if one has a marker for hepatic dysfunction. The problem is that there is no “creatinine” equivalent to assess the degree of functional hepatic impairment. One also must consider the hepatic extraction ratio and subsequent renal clearance of metabolites. Again, a specialty text in this area should be consulted.

Interspecies Extrapolations

The ultimate aim of any interspecies extrapolation would be to predict drug activity or toxicity in a new species not previously studied. There are two sources of error inherent to such an extrapolation. The first is that a drug’s pharmacokinetic profile (especially excretion, metabolism, and distribution) does not extrapolate across species without adjusting for some individual species characteristics. The second, which will always be problematic, is that the pharmacodynamic response of a drug may be very different between species and not at all related to pharmacokinetics. This latter concern may not be important for antimicrobial drugs since the pathogenic organisms being treated should have susceptibilities that are pathogen dependent and host independent. However, for drugs that interact with physiological functions that have species-specific receptor types and distributions, an estimate of pharmacokinetic parameters may not be sufficient to predict pharmacodynamic response.

There is a wealth of empirical observations that suggest that physiological functions such as O_2 consumption, renal glomerular filtration, cardiac output, etc., are not linearly correlated to the mass of an individual animal, both within and between species. That is, if one expresses any physiological function on a per kg body weight basis (e.g., GFR/kg), an *isometric* relationship would suggest that the parameter is constant. However, in the case of these physiological functions, such a relationship does not hold since the parameter on a mg/kg basis still is species dependent and not constant. A knowledge of body weight does not allow one to determine the value of the parameter across species with different body weights. However, if these parameters are expressed on a per unit surface area basis, many parameters such as GFR will be equivalent across species. More refined analyses suggest that the optimal scaling factor would be to a species’ Basal Metabolic Rate (BMR). Empirical observations suggest that BMR is a function of (body weight in Kg) raised to the 0.75 power [$GFR = \int -(BW_{kg})^{0.75}$]; when expressed on body surface area, the exponent is 0.67. An exponent of 0.75 is also theoretically predicted if metabolic functions are based on a model where substances in the body are transported through space-occupying fractal networks of branching tubes (e.g., the vascular system) that minimize energy dissipation and share the same size at the smallest level of structure (e.g., capillaries). Whatever the mechanism, these approaches are well suited for extrapolating drug disposition across species.

Equations where a parameter is related to a mathematical function (in this case, a power function) of a metric such as body weight is termed an *allometric* relationship. The extensive literature surrounding this question of how one “collapses” physiological parameters between species has created a field of study called *allometry*. Since most drug pharmacokinetic parameters are dependent upon some physiological function, they may also be scaled across species using these strategies. The method for doing this is to correlate the parameter of concern (e.g., GFR, Cl_B, T1/2 = most common) with body weight (BW) using the following allometric equation:

$$Y = a\,(BW)^b \tag{3.83}$$

where Y is the parameter of concern, a is the allometric coefficient and b the allometric exponent. The data is obtained using simple linear regression on $\log_{10}$ Y versus $\log_{10}$ BW, as depicted in Figure 3.23. The slope is the allometric exponent b and the intercept a. There is uniform agreement that for most physiological processes, the allometric exponent b ranges from 0.67 to 1.0. Note that if the parameter being modeled is an inverse function of a physiological process (e.g., T1/2), the exponent will be

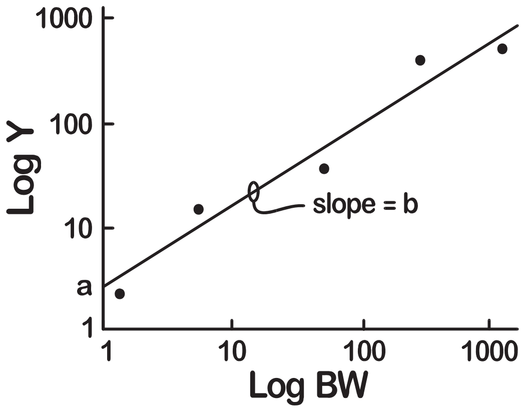

Figure 3.23 Basic log–log allometric plot of a biological parameter (Y) versus body weight (BW) with slope b and intercept a.

1 − b for that process. The coefficient a is actually the value of Y for a 1.0 kg BW animal (b = 0).

Numerous texts and research manuscripts deal with this topic in greater depth. There is an issue in human medicine where data is often extrapolated from small laboratory animals and dogs to larger humans, thus extrapolation error may be large. However, in veterinary medicine, one often interpolates because data are available in species of very different body masses. We recently published a large analysis of 85 drugs across multiple species that confirmed many of the factors just discussed (Huang et al., 2015). The important clinical take-home message to the veterinarian is that for equivalent effects, the dose may be greater in a smaller animal on a body weight basis. In cancer chemotherapeutics, doses are often expressed on the basis of body surface area, an adjustment that essentially compensates for the allometric exponent.

Conclusion

The purpose of this chapter was to introduce some core concepts of pharmacokinetics that determine the basis of dosage regimen construction in medicine. In most cases, a veterinarian will use the dosage recommended on the drug label. These concepts define where that dose originates, and importantly, how the clinician should consider adjusting it based on disease, therapeutic nonresponsiveness, or toxicity. The next chapter will present concepts linking a plasma concentration time profile to biological effect.

Mechanism of Drug Action and Pharmacokinetics/Pharmacodynamics Integration in Dosage Regimen Optimization for Veterinary Medicine

Pierre-Louis Toutain

Introduction

Pharmacokinetics (PK) studies the fate of drugs in the animal whereas pharmacodynamics (PD) studies the action of drugs from its interaction with receptors, to the effect on animal populations. Pharmacokinetic/pharmacodynamic (PK/PD) integration consists of describing and explaining the time course of the drug effect (PD) via the time course of its concentration in the plasma (PK). For a systemic drug, a tenet in pharmacology is that the plasma concentration controls the concentration at the site of action (the so-called *biophase* where receptors, pathogens, parasites, etc. are located) and that a proportional relationship exists between the plasma and biophase concentrations at equilibrium. This is why plasma concentration, which is easy to measure, can be used as an explicative variable of the in vivo drug effect when integrating PK and PD data in a PK/PD modeling approach (Figure 4.1). Plasma concentration, unlike the biophase concentration, is also easy to control with an appropriate dosage regimen and one of the main goals of PK/PD analysis is to precisely determine the dosage regimen (dose, dosage interval). The ultimate goal in controlling the plasma drug concentration (also termed drug exposure or internal dose) is to achieve some expected endpoint in terms of drug efficacy and safety.

The first part of this chapter addresses the question of drug pharmacodynamics with special emphasis on the relationship between drug concentration and intensity of action at the receptor level. The second part of this chapter is devoted to the in vivo situation and to the whole drug response. The classical dose-titration methods for dose determination and their limits are described with special emphasis on the alternative PK/PD approaches. The use of PK/PD modeling in studies of veterinary drugs has been reviewed (Riviere and Toutain, 2011; Toutain, 2002; Toutain and Lees, 2004) for antibiotics (Lees et al., 2006; McKellar et al., 2004; Toutain et al., 2002), angiotensin converting enzyme (ACE) inhibitors (Toutain and Lefebvre, 2004) and nonsteroidal antiinflammatory drugs (NSAIDs) (Lees et al., 2004a; Lees et al., 2004b). A glossary of pharmacodynamic terms and symbols is given in (Lees et al., 2004a; Neubig et al., 2003).

Types of Drug Targets

Most drugs act via an interaction with certain proteins either of the host or of the pathogen (Figure 4.2). Detailed discussions of drug mechanism of action are discussed in the specific chapters of this text. Exceptions are drugs in which the activity is based on physical properties, such as osmotic diuretics (e.g., mannitol) and antacids. Protamine that can be injected as an antidote of heparin acts as a physical antagonist by binding to it. Tiludronic acid is a biphosphonate used to prevent or to treat a variety of bone conditions. It binds to hydroxyapatite crystals and inhibits hydroxyapatite breakdown, suppressing bone resorption (Drake et al., 2008). General anesthetics were previously thought to produce their effect by simply dissolving in the lipid bilayer of the nerve membrane. It is currently acknowledged that all anesthetics act by either enhancing inhibitory signals or by blocking excitatory signals (for a review see Garcia et al., 2010). For intravenous anesthetics such as propofol and inhaled anesthetic as isoflurane, the target has been identified as the $\mathrm{GABA_A}$ receptor ($\mathrm{GABA_R}$), the most abundant fast inhibitory neurotransmitter receptor in the central nervous system. Ketamine and nitrous oxide inhibit ionotropic glutamate receptors, with the strongest effects being seen on the NMDA receptor subtype.

Four types of protein are targeted by drugs: *enzymes, carriers, ion channels,* and *receptors* (Figure 4.2). The term receptor should be reserved for regulatory proteins that play a role in intercellular communication. Thus, enzymes, ion channels, and carriers are not usually classified as receptors.

Enzymes such as cyclooxygenases are the target site for NSAIDs and their inhibition leads to the suppression of

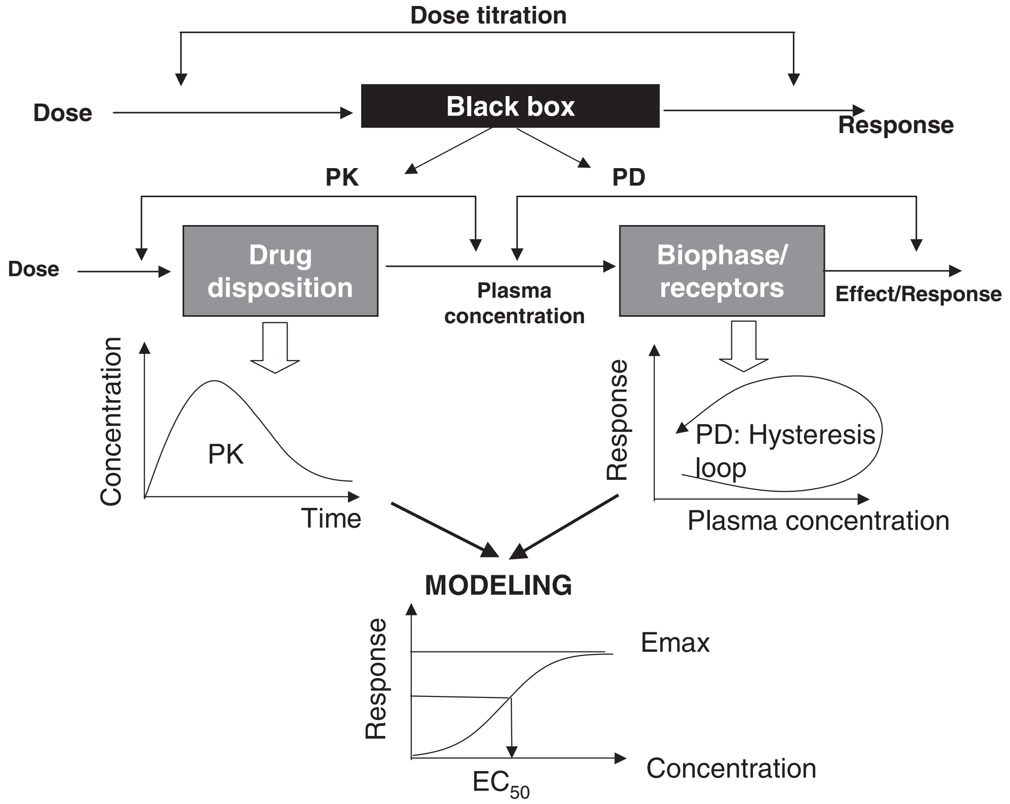

Figure 4.1 Dose–effect relationship versus PK/PD modeling. Both approaches aim at documenting the same relationship between dose and drug response. A dose–effect relationship is a black-box approach in which the dose is the explicative variable of drug response. In a PK/PD approach, the black box is opened, thereby enabling the two primary processes that separate dose from response to be recognized. In the first step (PK), the dose is transformed into a plasma concentration profile. In the second step (PD), the plasma concentration profile becomes the variable, which explains the drug response. The difficulty with the PK/PD approach is that the development of effect and plasma concentrations over time is usually not in phase. This means that a hysteresis loop is observed when the response is plotted against plasma concentrations and data modeling is required to estimate the PD parameters (E_{max}, ED_{50}, and slope).

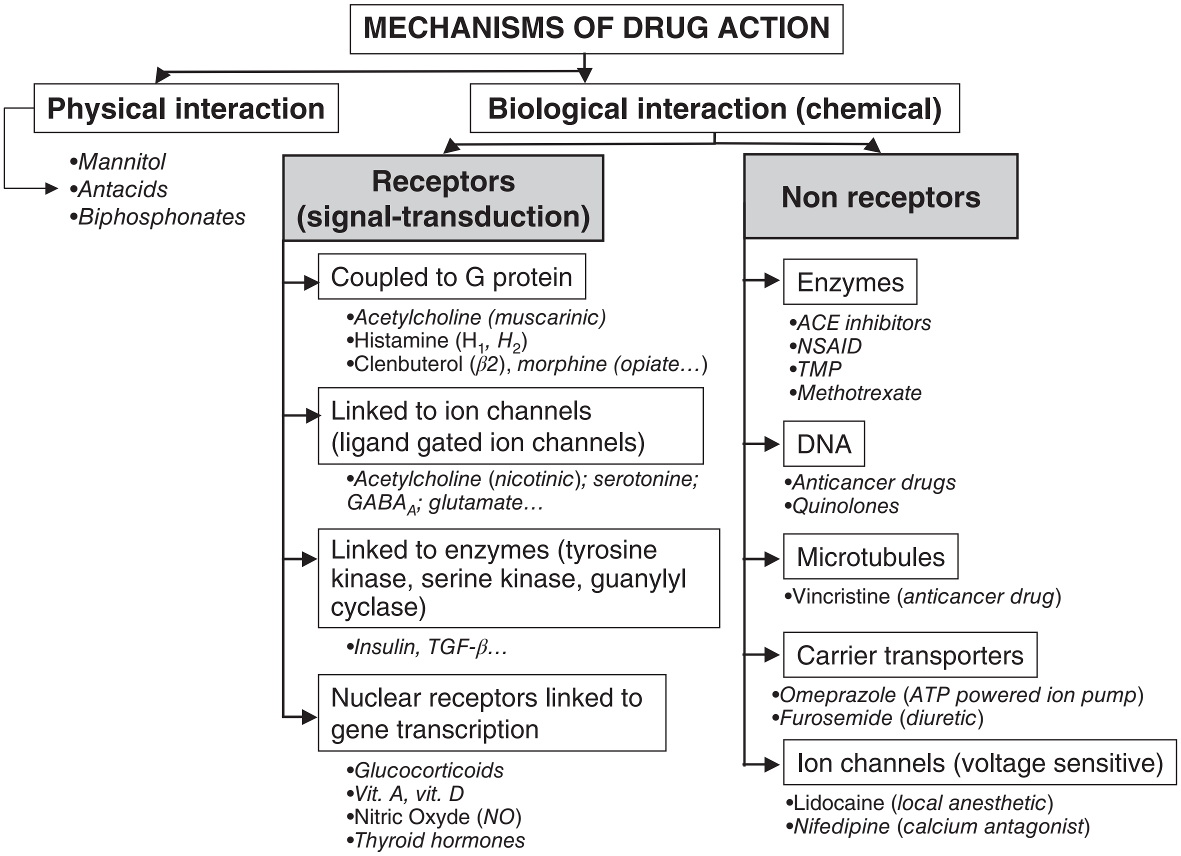
proinflammatory prostaglandins. Acetylcholine esterase, an enzyme that metabolizes acetylcholine at the receptor site, is a target site for cholinesterase inhibitors (neostigmine, physostigmine, etc.). Cholinesterase inhibitors act indirectly by preventing the enzyme from hydrolyzing acetylcholine. Other examples of enzymes serving as drug targets are dihydrofolate reductase for trimethoprim (an antibacterial) and angiotensin converting enzyme (ACE) for ACE inhibitors such as benazepril and enalapril. Antibiotics may act by inhibiting enzymes involved in cell wall biosynthesis, nucleic acid metabolism and repair, or protein synthesis, which is why antibiotics are generally more efficacious on multiplying bacteria.

Carriers (also termed membrane transport proteins) are target sites for many drugs. The $Na^+/K^+/2Cl^-$ symport in the nephron is the site of action of furosemide and other loop diuretics such as torasemide. Furosemide acts at the luminal surface of the thick ascending limb of the loop of Henle to prevent sodium chloride reabsorption. For all diuretics other than spironolactone, the biophase is urine, not plasma, and they need to gain access to the lumen of the nephron to develop their diuretic action. This explains why in renal failure, the dose often needs to be substantially increased, not decreased as for other drugs. ATP-powered ion pumps such as the sodium pump (Na^+/K^+ ATPase) are the target sites for cardioactive digitalis and the Na^+/H^+ pump in the gastric parietal cell is the target site for proton pump inhibitors such as omeprazole.

Some drugs, such as local anesthetics, produce their effects in the nervous system and in the heart (Grace and Camm, 2000; Sills, 2011) by directly interacting with *ion channels*. They inhibit *voltage-gated* Na^+ *channels* in sensory neurons by binding to specific sites within the Na^+ channel and produce a direct effect by incapacitating the protein molecule. Their affinity varies with the gating state of the channel, with a high affinity when the channels are opened and inactivated during action potentials at high frequency, as occurs during pain or a cardiac arrhythmia. Most antiepileptic drugs act on voltage–gated Na^+ channels and voltage-dependent



MECHANISMS OF DRUG ACTION
Physical interaction
•Mannitol
•Antacids
•Biphosphonates
Biological interaction (chemical)
Receptors (signal-transduction)
Non receptors
Coupled to G protein
•Acetylcholine (muscarinic)
•Histamine (H_1, H_2)
•Clenbuterol (β2), morphine (opiate…)
Linked to ion channels (ligand gated ion channels)
•Acetylcholine (nicotinic); serotonine; $GABA_A$; glutamate…
Linked to enzymes (tyrosine kinase, serine kinase, guanylyl cyclase)
•Insulin, TGF-β…
Nuclear receptors linked to gene transcription
•Glucocorticoids
•Vit. A, vit. D
•Nitric Oxyde (NO)
•Thyroid hormones
Enzymes
•ACE inhibitors
•NSAID

•Anticancer drugs
•Quinolones
Microtubules
•Vincristine (anticancer drug)
Carrier transporters
•Omeprazole (ATP powered ion pump)
•Furosemide (diuretic)
Ion channels (voltage sensitive)
•Lidocaine (local anesthetic)
•Nifedipine (calcium antagonist)

Figure 4.2 Mechanisms of drug action. For most drugs, the drug action is mediated by some biological interaction with a macromolecule of the cell, often a protein. Different proteins are involved as drug targets and the term receptor is only used when the interaction triggers a cascade of events for signal transmission.

gated calcium channels are the main target of most calcium-channel blockers, such as the antiarrhythmic drugs verapamil and amlodipine. This mechanism of drug action on ion channels should not be confused with that of *ligand-gated ion channels,* which function as ionotropic receptors (see Section Macromolecular Nature of Drug Receptors).

Other nonreceptor/nonprotein targets as sites of action are nucleic acids for drugs such as actinomycin D, an antineoplastic antibiotic. DNA is also the target for a number of antibiotics (quinolones) as well as mutagenic and carcinogenic agents.

Drug Receptor and Ligand as Agonist or Antagonist

A receptor is a molecule or a polymeric structure on the surface of or inside a cell that specifically recognizes and binds an endogenous compound. Binding sites are three-dimensional structures, forming pockets or grooves on the surface of protein that allow specific interactions with compounds known as *ligands*, which are molecules of complementary shape to the protein binding site (lock and key analogy). Receptors possess an effector system (also termed signal-transduction pathways). In this they differ from *acceptors* which are molecules without signal-transduction pathways (e.g., serum albumin), characterized by a binding process that is not followed by a physiological response.

Endogenous neurotransmitters, such as hormones, act as molecular messengers and are endogenous ligands. Drugs may be viewed as exogenous ligands. After attachment to a receptor site, a drug may produce a cascade of biochemical events that result in drug action. A drug is said to be an *agonist* when it produces a measurable physiological or pharmacological response characteristic of the receptor (contraction, relaxation, secretion, enzyme activation, etc.). If a drug binds to the same site as the endogenous ligand, the drug is said to be a *primary agonist,* in comparison to an *allosteric agonist* which binds to a different region of the receptor. Most anesthetic drugs allosterically modulate $GABA_R$ and disrupt corresponding physiological circuits. A *full agonist* produces a maximal effect under a given set of conditions whereas a *partial agonist* produces only a submaximal effect regardless

Drug having selectivity for the resting state of the receptor and reducing the constitutive activity of the receptor

Figure 4.3 Schematic representation of the spectrum of drug effect from full agonist (maximum positive effect) to full inverse agonist (maximum negative effect). Such a spectrum is only seen if a constitutive receptor activity exists which can be inhibited by an inverse agonist (see Figure 4.9 for explanation). According to the "receptor theory", drugs may be agonists or antagonists. A full agonist produces full receptor activation leading to a maximal response; a partial agonist produces a submaximal response and possible blockade of a full agonist activation. An antagonist does not produce any physiological response but is able to block the response of an endogenous ligand or exogenous agonist. In the framework of the two-state model, any drug is viewed as an agonist, and an antagonist is a neutral agonist producing no response. According to this model "efficacy" is genuinely explained by the relative affinity of the drug for one of the states of the receptor (activated or resting state) and inverse agonists are drugs showing selectivity for the resting state of the receptor. An inverse agonist acts as an antagonist but has the supplementary property over a classical antagonist of reducing receptor-mediated constitutive activity.

of the amount of drug applied. For opioid receptors, morphine and fentanyl are full agonists, able to initiate strong analgesia, while buprenorphine is a partial agonist (Lees et al., 2004b). Even if buprenorphine is unable to achieve the same level of analgesia provided by a maximally effective dose of full agonists, it may be preferred for postsurgical analgesia because its effect is of long duration and adverse effects are minimal.

In contrast to an agonist, some drugs may be unable to trigger any action on their own, after attachment to a receptor site, but are able to block the action of other agonists. These "silent drugs" are termed *antagonists*; most drugs used in therapeutics are receptor antagonists and prevent the action of natural agonists (neurotransmitters, hormones, etc.). Some drugs may be both agonist and antagonist, for example butorphanol, a central-acting opioid analgesic, is mainly an antagonist at the *mu* receptor but is an agonist at the *kappa* receptor. Two forms of antagonism can be distinguished: *competitive* and *noncompetitive antagonism*. In competitive antagonism, antagonists act on the same receptor as the agonist; this is said to be reversible when it can be surmounted by increasing the concentration of the agonist. Examples of therapeutic agents acting by competitive antagonism are atropine (an antimuscarinic agent) and propranolol (a beta blocker). In irreversible (competitive) antagonism, a net displacement of the antagonist from its binding site cannot be achieved by increasing the agonist concentration and, operationally, it resembles noncompetitive antagonism. This occurs when the antagonist is bound covalently and irreversibly to its receptor binding site. Although there are few drugs of this type, irreversible antagonists are used as experimental probes for investigating receptor function. *Noncompetitive antagonism* refers to the situation where a drug blocks the cascade of events, normally leading to an agonist response, at some downstream point. This occurs with Ca^{2+} channel blockers, such as nifedipine, which prevent the influx of calcium ions through the cell membrane and nonspecifically block any agonist action requiring calcium mobilization, as in smooth muscle contraction. The concept of *physiological antagonism* refers to the interaction of two drugs whose opposing actions on a physiological system tend to cancel each other out. For example, histamine acts on receptors of the parietal cells of the gastric mucosa to stimulate acid secretion, while omeprazole blocks this effect by inhibiting the proton pump.

Antagonists were viewed solely as “silent ligands” until the discovery of the so-called inverse agonists. An inverse agonist is a drug that acts at the same receptor as that of an agonist, yet produces an opposite effect (see Section Drug Receptor Theories: from the Occupancy Theories to the Two-State Model for the mechanism of inverse agonist action). Figure 4.3 summarizes the spectrum of activities that ligands can display.

Drug Affinity, Efficacy and Potency

The concentration–effect relationship is determined by two features of the drug–receptor interaction, namely drug *affinity* and drug *efficacy*. The affinity of a drug is its ability to bind to a receptor. Affinity is determined by the chemical structure of the drug and minimal modification of the drug structure may result in a major change in affinity. This is exploited to discover new drugs. Affinity determines the concentration of drug required to form a significant number of drug–receptor complexes that in turn are responsible for drug action. The numerical representation of affinity for both an agonist and an antagonist is the *constant of affinity,* denoted by Ka (dimension M^{-1}, i.e., liter per mole). A Ka of $10^7 M^{-1}$ means that one mole of the ligand must be diluted in 10^7 liters of solvent to obtain a concentration of the free ligand able to saturate half the maximal binding capacity of the system. The reciprocal of Ka is the equilibrium *dissociation constant* of the ligand–receptor complex, denoted by Kd (dimension M i.e., mole per liter). A Kd of 10^{-7}M means that a free ligand concentration of 10^{-7} mole per liter is required to saturate half the maximal binding capacity of the system. The lower the Kd value of a drug, the higher the affinity for its receptor.

Radioactive receptor ligands (radioligands) or fluorescent probes are used to accurately determine receptor affinity. The relationship between bound and free ligand may be described by a hyperbolic equation (Figure 4.4) corresponding to the Michaelis Menten equation:

$$Bound = \frac{B\max \times Free}{Kd + Free} \tag{4.1}$$

Where B_{max} (a parameter) represents the maximal binding capacity (the total number of receptors), *Free* is the molar concentration of the free ligand, *Bound* is the bound ligand concentration and *Kd* (a parameter) is the equilibrium constant of dissociation.

From this equation, the receptor occupancy (i.e., the fraction of receptor occupied) can be described by:

$$fraction\ occupied = \frac{Bound}{B\max} = \frac{Free}{Free + Kd} \tag{4.2}$$

This is known as the Hill–Langmuir equation.

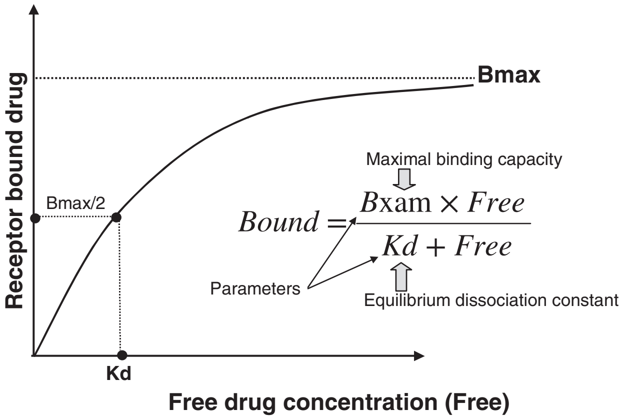

Figure 4.4 Relationship between free drug concentration (*Free*) (independent variable), that is the driving concentration, and receptor-bound drug (dependent variable). Affinity of a drug for its receptor is expressed by Kd (a low Kd means a high affinity). B_{max} indicates the maximal binding capacity of the receptor.

The generation of a response for the drug–receptor complex is governed by a property named efficacy. *Efficacy* is the drug's ability, once bound, to initiate changes that lead to the production of responses. It is a property of the ligand/receptor pair. This term is used to characterize the level of maximal response (E_{max}) induced by an agonist. In contrast, a pure antagonist has no *intrinsic efficacy* because it does not initiate a change in cell functions. This concept of efficacy is not to be confused with the drug's *clinical efficacy* whereby an antagonist may be fully efficacious. This is because blocking the binding of an endogenous agonist to the receptor by an antagonist may be clinically useful. *Potency* corresponds to the concentration of drug required to achieve a given effect. It is expressed by the EC_{50} (or the IC_{50} if the effect is an inhibition), that is the concentration of an agonist which produces 50% of the maximum possible response for that agonist (Figure 4.5). Potencies of drugs vary inversely with the numerical value of their EC_{50} and the most potent drug is the one with the lowest EC_{50}.

The concept of drug efficacy and potency is also used in a clinical context. Drug efficacy is the property of most interest to clinicians who are looking for the most efficacious drug. For example, it was shown using an inflammatory model in horses that flunixin was more efficacious than phenylbutazone in induced lameness (Toutain et al., 1994). For some drugs such as loop diuretics, there is actually a maximum possible effect that can be obtained regardless of how large a dose is administered and this is termed the *high ceiling effect.* When different drugs within a series are compared, the most potent drug is not necessarily the most clinically efficacious (Figure 4.6). For example, butorphanol is more potent but less efficacious than morphine for analgesia. Another example is glucocorticoids. All glucocorticoids

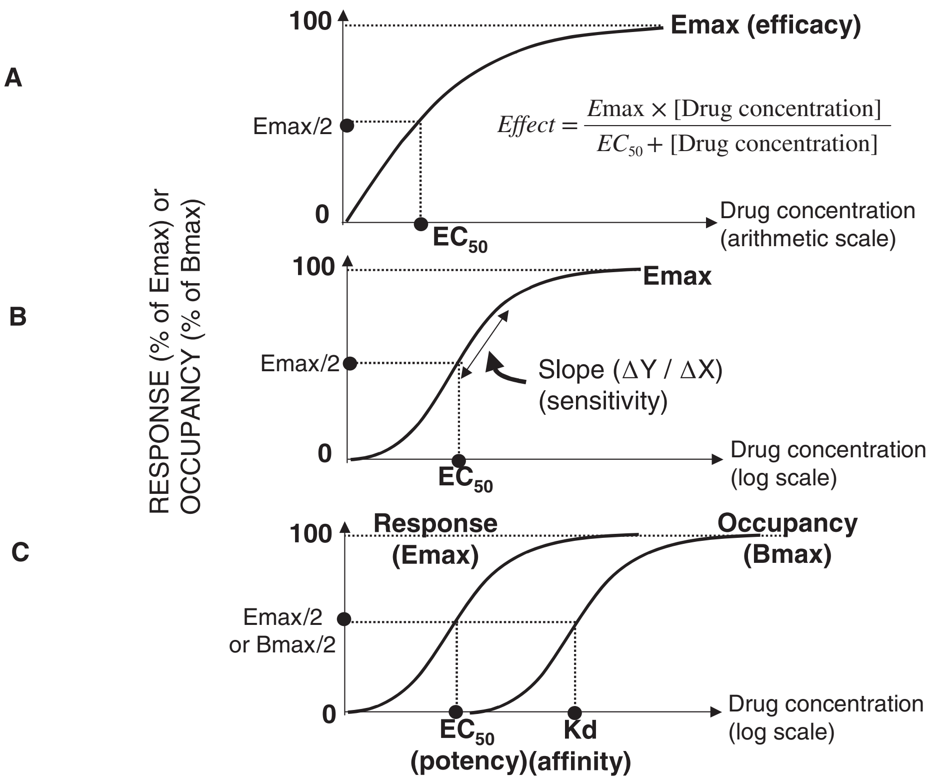

Figure 4.5 The dose–response relationship and definition of the three main pharmacodynamic parameters.
(A) When the drug response (arithmetic Y axis) is plotted against the tested dose (arithmetic X axis), a hyperbolic relationship is often observed with a maximal effect denoted E_{max}. EC_{50} is the concentration that produces an effect equal to half E_{max}.
(B) When the same data are represented using an X log scale, the relationship becomes sigmoidal with a more or less steep slope. The advantage is to compress the dose scale and to visualize the slope more easily. A sigmoidal curve allows the definition of three drug parameters, namely E_{max}, ED_{50}, and the slope (ΔY/ΔX). E_{max} describes the drug efficacy and EC_{50} describes the drug potency. The slope (measured by the *n* of the Hill equation; see Equation 4.4 in the text) indicates the sensitivity of the dose–effect curve. The slope of the curve is involved in the drug selectivity (see Figure 4.11).
(C) This plot shows that the concentration effect curve is situated to the left of the free concentration (occupancy)-bound concentration curve with EC_{50} generally $\ll$ Kd.

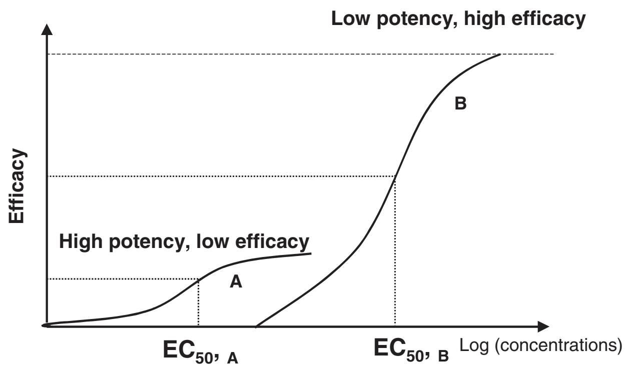

Figure 4.6 Drug potency versus drug efficacy. These two terms are often confused. Potency is expressed in terms of concentration (X axis) and EC_{50} is the parameter measuring drug potency. Efficacy (Y axis) expresses the level of response with a maximal possible effect (E_{max}). Efficacy is the parameter of interest for a clinician but potency may be a limiting factor if the drug has to be administered in a small volume. Here drug A has a higher potency than drug B but has a lower efficacy.

are able to totally suppress the endogenous cortisol secretion (adrenal suppressive effect), as well as to ensure a full eosinopenia, thymus involution and in regard to these suppressive endpoints, they all have the same pharmacological efficacy. However, their potencies are very different, with dexamethasone, betamethasone, and triamcinolone acetonide being 20 to 30-fold more potent than cortisol, whereas prednisolone and methylprednisolone are only four to fivefold more potent than cortisol. A low potency is only a disadvantage when the effective dose is too large to be convenient; for example for a spot-on, eye drop or intraarticular administration, the volume to be administered must be small and only relatively potent drugs can be administered in this way.

Drug Specificity and Selectivity

The drug receptor interaction is responsible for the *specificity* and *selectivity* of drug action. When the drug acts only on a single target (enzyme, receptor, etc.), it is said to be specific. *Specificity* is linked to the nature of the drug–receptor interaction and more precisely to the macromolecular structure of the receptors (or enzymes). As receptors are generally proteins, the diversity in three-dimensional shape required for ligand specificity is provided by the polypeptide structure. The recognition of specific ligands by receptors is based on the complementarity of the three-dimensional structure of the ligand and a binding pocket on the macromolecular target. The shapes and actions of receptors are currently being investigated by X-ray crystallography and computer modeling.

Specificity is rare. Most drugs can display activity towards a variety of receptors and are more often selective than specific. For example histamine antagonists produce several effects, such as sedation and prevention of vomiting, which do not depend on histamine antagonism. *Selectivity* is related to the concentration range. The drug may be specific at a low concentration if it activates only one type of target, whereas several targets may be involved simultaneously (activated, inhibited, etc.) if the drug concentration is increased. This is the case with NSAIDs and inhibition of the different subtypes of cyclooxygenases (COX-1 vs. COX-2 isoenzymes) (Figure 4.7). Cortisol possesses both glucocorticoid and mineralocorticoid properties and cortisol at pharmacological dose causes unwanted side effects, such as fluid–electrolyte imbalance, which is the reason why it cannot be used as an antiinflammatory drug. This is due to the close structural relationship of the nuclear glucoreceptor (GR) and the mineralocorticoid receptor (MR). The in vivo natural ligand of the MR is aldosterone. A biological paradox is that the affinity for the MR is similar for aldosterone and cortisol, while cortisol concentration in epithelial tissues is much higher (100–1000 fold) than aldosterone concentration, raising the issue of a possible unwanted binding of cortisol to the MR. Actually, the in vivo selectivity of aldosterone for the MR exists despite its much lower concentration and is of enzymatic origin; it is determined by the intracellular metabolism of cortisol into cortisone, an inactive metabolite with a low affinity for the MR. This inactivation of cortisol is carried out by the unidirectional 11β-hydroxysteroid dehydrogenase (11βHSD) of type 2, an enzyme expressed in the epithelial aldosterone target cell. 11βHSD can be inhibited by various substances, such as furosemide and licorice. For synthetic glucocorticoids, it was desirable to separate the gluco- from the mineralocorticoid effect and selectivity for the GR (associated to the antiinflammatory effect) was obtained by structural modification of the cortisol; first an increase of the selectivity was obtained by the introduction of Δ1-dehydro configuration (as for prednisolone) and then by adding a hydrophobic residue in position 16 as a 16-α-methyl group for dexamethasone or a 16-β-methyl group for betamethasone and beclomethasone(Farman and Bocchi, 2000).

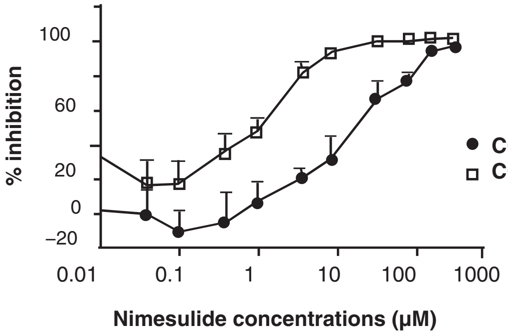

Figure 4.7 Drug selectivity. For a non steroidal antiinflammatory drug (NSAID) such as nimesulide, the antiinflammatory properties are linked to the inhibition of cyclooxygenase (COX). There are two isoforms of COX, namely COX-1 and COX-2. COX-2 is an inducible enzyme formed at the site of inflammation and producing proinflammatory prostaglandins such as PGE$_2$, whereas COX-1 is a constitutive enzyme that performs a range of housekeeping functions. The selective inhibition of COX-2 is considered the primary action to be achieved for a NSAID and the nonselective inhibition of COX-1 is considered detrimental, especially for the digestive tract (ulceration). This COX-2/COX-1 selectivity can be explored ex vivo using a whole blood assay (Toutain et al., 2001b). When this assay was conducted using canine blood, the production of TxB$_2$ by platelets was used to measure COX-1 inhibition and the production of PGE$_2$ from LPS-stimulated leukocytes was used to measure COX-2 inhibition. The IC$_{50}$ values were 1.6 ± 0.4 µM for COX-2 and 20.3 ± 2.8 µM for COX-1, indicating that nimesulide is about 12 times more potent for COX-2 than for COX-1 isoenzymes. Nevertheless, nimesulide cannot be considered as a selective COX-2 inhibitor but only as a preferential COX-2 inhibitor. COX-2 would need to be almost totally inhibited to obtain a full antiinflammatory effect and this is impossible to achieve without any COX-1 inhibition. *Source:* Toutain 2001b. Reproduced with permission of John Wiley & Sons, Inc.

Lack of selectivity in vivo may lead to an overall complex and unpredictable pharmacological response and even undesirable side effects. This is the case, for example, for drugs administered as racemic mixtures of stereoisomers. Stereoisomers can exhibit not only very different potency and efficacy for a given effect, but also very different dispositions with possible interconversion between stereoisomer, rendering it difficult to predict the net effect of the drug and its time development. For antibiotics, antiparasitics, and similar drugs, the concept of selectivity is twofold: selectivity regarding the host versus selectivity regarding the target. Pathogen selectivity is generally expressed in terms of the spectrum of activity using an classification tool such as the staining properties (Gram positive vs. Gram negative) or a taxonomical classification (family, species, strains, etc.). Selectivity regarding the host is also an important characteristic to minimize the toxicity of antibiotics and insecticides. For example, penicillin inhibits key enzymes (transpeptidases, carboxypeptidases) involved in the peptidoglycan biosynthesis required for synthesis of the bacterial wall. These enzymes do not exist in mammals, ensuring an excellent selectivity and safety of this class of antibiotics in mammals.

Assessing the therapeutic usefulness of a new drug requires the determination of its full spectrum of biological activities towards a variety of relevant targets. The next task is then to explore this in vivo, and select an appropriate dosage regimen that maintains the plasma drug concentration within the range in which only the desired response is expressed (i.e., within the so-called *therapeutic window*).

Chemical Forces and Drug Binding

Several chemical intermolecular forces such as ionic bonds, hydrogen bonds, and Van der Waals forces may be involved in reversible binding of the drug to the receptor. In contrast, drug–receptor interactions involving covalent bond formation (very tight) are generally irreversible. Covalent binding to receptors is relatively rare. However, covalent binding is more frequent for drugs acting on enzymes. COX-1 inhibitors are generally reversible, although aspirin acts as a noncompetitive inhibitor of platelet COX-1 through a covalent binding mechanism. This is achieved by irreversible acetylation and explains the duration of the action of aspirin on blood coagulation. As platelets have no nucleus, the effect of aspirin is reversed by the production of new platelets. Omeprazole (a proton pump inhibitor) is another example of irreversible binding to an enzyme (H^+,K^+-ATPase). Drugs that bind covalently to DNA (alkylating agents) are extensively used as anticancer drugs.

Since many drugs contain acid or amine functional groups that are ionized at physiological pH, ionic bonds are formed by the attraction of opposite charges in the receptor site. Ionic bonds are the strongest noncovalent bonds. The attraction of opposite charges is brought about by polar–polar interactions as in hydrogen bonding. Although this electrostatic interaction is weaker than the ionic bond, an important feature of hydrogen bonding is the structural constraint. Thus the formation of hydrogen bonds between a drug and its receptor provides some information about the three-dimensional structure of the resulting complex. The same forces are responsible for the shape of the protein and for its binding properties, so shape influences binding and, in turn, binding can influence protein shape. The ability of protein to change shape is called allostery.

Macromolecular Nature of Drug Receptors

Many receptors are transmembrane proteins embedded in the lipid bilayer of cell membranes. They have two functions: ligand binding and message transduction. Transmembrane receptors include metabotropic and ionotropic receptors (Figure 4.8). The four superfamilies of receptor proteins include: (i) ligand-gated ion channels, which are membrane-bound receptors, directly linked to an ion channel; (ii) G-protein coupled receptors, which are membrane-bound receptors coupled to G-proteins; (iii)tyrosine kinase-linked receptors, which are membrane bound receptors containing an intrinsic enzymatic function (tyrosine kinase activity) in their intracellular domain; and (iv) transcription factor receptors that are intracellular receptors regulating gene transcription.

The activation of metabotropic receptors (tyrosine kinase receptors and G-protein-coupled receptors) leads to some changes in metabolic processes within the cell, whereas ionotropic receptors directly open or close an ion channel. When an ionotropic receptor is activated, it opens a channel that immediately allows ions such as Na^+, K^+, or Cl^- to flow. In contrast, when a metabotropic receptor is activated, a series of intracellular events is first triggered that may also subsequently result in ion channel opening.

G-protein-coupled receptors (GPCRs), also known as *seven transmembrane receptors (7TM receptors)*, transduce an extracellular signal (ligand binding) into an intracellular signal (G-protein activation). The signal is transferred via conformational alterations to a member of the family of G-proteins. G-proteins may act directly on an ionic channel or activate an enzymatic system (adenylyl cyclase, guadenylyl cyclase, phospholipase C, etc.) to release a range of second messengers (cAMP, cGMP, IP3, etc.), which ultimately permits certain ions to enter or leave the cell. Muscarinic acetylcholine receptor, adrenoceptors (α_1, α_2, β), dopamine, histamine, opioids, ACTH, and other receptors are examples of 7TM receptors.

The so-called *receptor tyrosine kinase* (RTK) family is also a class of metabotropic cell surface receptors, which exert their regulatory effect by phosphorylating different effector proteins. An RTK consists of an extracellular binding site and an intracellular portion with enzymatic activity (tyrosine kinase, serine kinase) and usually spans the cell membrane once only. Tyrosine kinase enzymes can transfer a phosphate group from ATP to a tyrosine residue in an intracellular protein to increase its phosphorylation. Protein phosphorylation is one of the underlying mechanisms regulating protein function. It can alter the biological properties or the interaction of proteins with other proteins or peptides. This family of receptors includes insulin, IGF-1, cytokines, and epidermal growth factor. The hormones and growth factors that act on this class of receptors are generally growth promoting and function to stimulate cell division.

Ionotropic receptors activate transmembrane ion channels. They contain a central pore, which functions as a ligand-gated ion channel. Nicotinic cholinergic receptor, $GABA_A$ receptor, and glutamate, aspartate, and

Figure 4.8 Types of receptors and signaling mechanisms.
(A) Ion channels receptors. Ion channels inhibitors or ligand-gated receptors (ionotropic receptors) are proteins forming on aqueous pores in the plasma membrane. Ligand binds at a specific site on the receptor. This leads to conformational changes, which open the channel and allow ions to flow into the cell. The change in ion concentration within the cell triggers cellular response. These receptors react in milliseconds. This type of receptor is not to be confused with voltage-gated ion channels that are not considered to be receptors (no signal transduction).
(B) G-protein-coupled receptors. G-protein-coupled receptors (GPCR) are single polypeptide chains forming seven transmembrane domains within the membrane with a segment able to interact with G-proteins.
B1 (inactive state): G-protein (GP) is attached to the cytoplasmic side of the membrane and is inactive as long as a ligand binds to GPCR. An ion channel or enzymes are possible terminal effectors of GPCR.
B2 (active state) steps 1 to 4:
Step 1: binding of a ligand changes the shape of the GPCR that interacts with a GP.
Step 2: interaction causes activation of GP, with guanosine diphosphate (GDP) being exchanged against guanosine triphosphate (GTP).
Step 3: the activated GP (Gα-GTP) moves either towards an enzyme, or directly modulates the conductance of an ionic channel (e.g., muscarinc receptor).
Step 4: when an enzyme is activated (adenylyl cyclase, guanylyl cyclase, etc.) a second messenger (Ca^{2+}, cAMP, cGMP, etc.) is generated and can mediate an action. Then G-protein hydrolyses GTP back to GDP.
The advantage of this signal transduction pathway is twofold: signal amplification and signal specificity.
(C) Tyrosine kinase receptors
C-1 (inactive state): tyrosine kinase receptors (TKR) are transmembrane receptors consisting of individual polypeptides each with a large extracellular binding site and an intracellular tail with an enzyme (tyrosine (Tyr) kinase, serine kinase).
C-2 (active state): when a ligand binds to both receptors, the two receptor polypeptides aggregate to form a dimmer. This activates the tyrosine kinase part of the dimmer. Each uses ATP to phosphorylate the tyrosines on the tail of the other polypeptide as well as other down-stream signaling proteins. The receptor proteins are now recognized by relay proteins inside the cell. Relay proteins bind to the phosphorylated tyrosines and may activate different transduction signals.
(D) Nuclear receptors. Intracellular receptors are located in the cytoplasm or the nucleus (NO, thyroid hormones, steroids, etc.) the signal molecule (lipophilic) must be able to cross the plasma membrane. The ligand binds to a receptor called a nuclear receptor, although some are located in the cytosol (e.g., glucocorticoid receptors) and migrate to the nucleus after binding a ligand. This activation pathway leads to a long-lasting effect, usually over several hours.

glycine receptors are ligand-gated ion channels. The most important veterinary antiparasitic drugs (ivermectins, fipronil) act on ligand-gated anion channels and imidacloprid acts on a ligand-gated cation channel (Raymond and Sattelle, 2002). For ivermectin, glutamate-gated chloride channels have been localized to the pharynx of *Caenorhabditis elegans* and it was suggested that ivermectin could inhibit the pharyngeal pumping in *Haemonchus contortus* that is required for its feeding (Forrester et al., 2004).

Transcription factor receptors such as those for steroid hormones, thyroid hormone, vitamin D, or retinoids receptors are intracellular proteins serving as transcription factors. After binding the ligand, for example a steroid hormone, the activated receptors translocate to the nucleus and bind to a DNA sequence called the *response element* and initiate the transcription of specific gene(s).

Receptor Types and Subtypes

Endogenous neurotransmitters (acetylcholine, norepinephrine, etc.) often bind to more than one type of receptor. This allows the same signaling molecule to produce a variety of effects in different tissues. For example acetylcholine acts via both G-protein receptors (e.g., M_2 muscarinic receptors in the heart) and ligand-gated channels (nicotinic muscle receptors). Historically, the classification of receptors has been based on their effect and relative potency towards selective agonists and antagonists. Now the association of molecular biology and cloning techniques has led to the discovery of novel receptor subtypes and their expression as recombinant proteins has facilitated the discovery of more selective drugs. The International Union of Basic and Clinical Pharmacology (IUPHAR) has a committee on receptor nomenclature and drug classification and regularly publishes updated reviews and a compendium in its Journal (*Pharmacological Reviews*; see www.iuphar.org) (Neubig et al., 2003).

Drug Receptor Theories: from the Occupancy Theories to the Two-State Model

Drug receptor theories consist of a collection of evolving models that correspond to the historical progression of knowledge and permit qualitative and quantitative description of the relationship between drug concentrations and their effect. Before the advent of molecular biology, the various effects of agonists and antagonists were described by operational mathematical modeling, that is with no or minimal mechanistic considerations (a black-box approach). Effects were measured on isolated tissue in an organ bath chamber and the collected data were modeled using relatively simple equations derived from the law of mass action, as in Equation 4.1.

Occupancy Theory was the first model and was proposed by Clark in 1923 (Rang, 2006). The receptor–ligand interaction was described as a bimolecular interaction and the receptor–ligand complex was considered responsible for the generation of an effect. This model assumes that the drug response is a linear function of drug occupancy at the receptor level. Consequently, the drug has to occupy all receptors to achieve a maximal effect (E_{max}), and the response is terminated when the drug dissociates from the receptor. Thus, in the equation for receptor binding (see Equation 4.1) the terms B and B_{max} can be replaced with E (effect) and E_{max}, leading to:

$$Effect = E\max \times \frac{[Drug]}{kD + [Drug]} \tag{4.3}$$

in which *Effect* (the dependent variable) is the observed effect; E_{max} (a parameter) is the maximal possible effect for that system; *Kd* is a parameter measuring affinity and *Drug* is the drug concentration, that is the independent variable. In this simple occupancy model of drug action, the concentration of drug required to produce 50% of the maximal effect (i.e., the EC_{50}) is numerically equal to the dissociation constant (i.e., Kd).

This equation describes the classical hyperbolar agonist–effect relationships. These relationships are often presented on a log scale, in which case they are sigmoidal (see Figure 4.5). It should be noted that some drugs do not follow the classical monotonic dose–effect relationship but rather a U-shaped relationship. Here, drugs may cause low-dose simulation and high-dose inhibition of response (or the inverse) leading to the concept of *hormesis* (for details see (Calabrese and Baldwin, 2003), a challenging concept in toxicology.

The occupation model of Clark was only confirmed in a limited number of cases. As a rule, the physiological response produced by a ligand is not directly proportional to occupancy and it was evident that some drugs acting at the same receptor could elicit different maximal effects at maximal receptor occupancy leading to the notion of *partial agonist versus full agonist*. To account for these discrepancies, which could not be explained by the occupation theory, Ariens and Simonis, (1954) suggested the existence of a proportionality factor, termed the *intrinsic activity*, between the amount of ligand–receptor complex and the observed effect. At almost the same time, Stephenson (1956) introduced the terms of *affinity* for the binding step and the concept of (molecular) *efficacy* for the production of a response. In this concept, a maximal response did not necessarily correspond to 100% receptor occupancy but could occur when only a few receptors were occupied. This led to the concept of *spare receptors* or a *receptor reserve*; thus activation of fewer than 1% of receptors at the skeletal neuromuscular junction, for example, is enough to elicit an action potential and maximal contraction of muscle fiber. According to Stephenson's concept, the final effect of a drug is not directly proportional to the number of receptor–ligand complexes but is linked to the generation of an intermediary step termed *stimulus*, and it is the stimulus that is proportional to the amount of receptor–ligand complex. Finally, the stimulus is translated by the tissue into a more or less amplified response. Thus the efficacy of an agonist, according to Stephenson, is the parameter that indicates its ability to generate the stimulus instead of the final response in Ariens' theory. These concepts of intrinsic activity and efficacy have been historically important to our understanding of the mechanism of drug action because they acknowledge two different properties of molecules: the affinity of the ligand for the receptor (as measured by its Kd) that determines the receptor occupancy, and a second property that is the ability to activate the receptor once bound. Thus a partial agonist may show higher affinity than a full agonist but be less effective in generating a biological response because its intrinsic activity is lower than that of a full agonist (Figure 4.6). Currently, with the advent of molecular biology and the availability of recombinant receptor systems, it is possible to better understand how an agonist actually works and physiologically based models rather than the black-box approach are used to explain the concept of efficacy. Currently, the most generic model is known as the *two-state* model (Figure 4.9).

The two-state model of drug action is consistent with most observations of agonists and antagonists and is genuinely able to explain the nature of inverse agonists and the existence of a spontaneous (constitutive) activity of receptors. Briefly, this model assumes that the receptor molecule exists in two extreme conformations with the active and inactive forms in dynamic

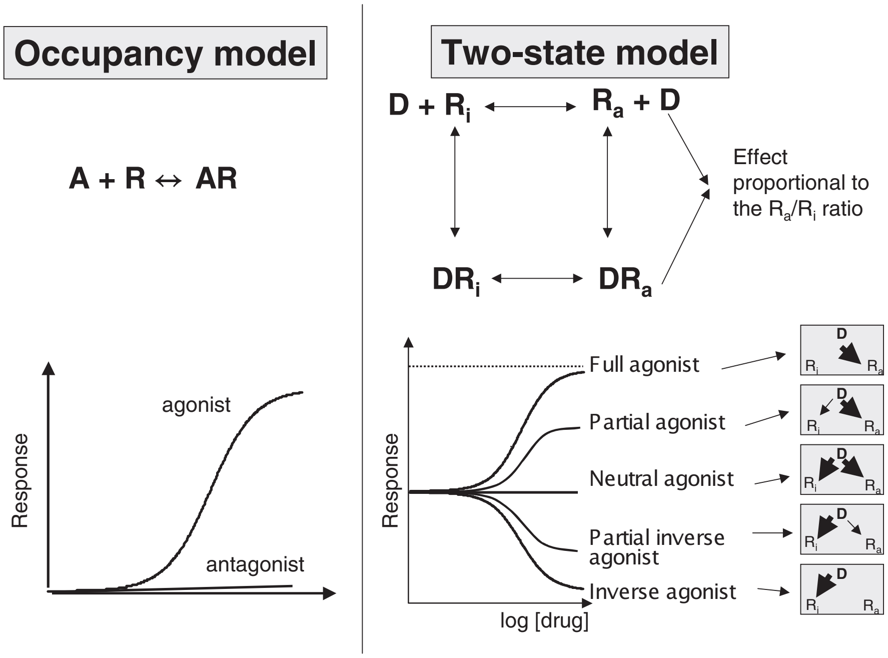

Figure 4.9 Model of receptor activation: the graded activation model (left) versus the simple two-state model (right). The graded activation model implies that agonists can induce different degrees of conformational changes in the receptor (R) and thus different levels of response. In this model, the unliganted receptor is silent (no basal activity) while in the two-state model there is a preexisting resting and an active state. For the occupancy model, the level of response is explained by the concept of efficacy (see Figure 4.3) and an antagonist is a drug with a null (molecular) efficacy but that blocks access to the receptor of other ligands. In the two-state model, a receptor can switch between two conformational states that are in equilibrium: an active state (Ra) and an inactive state (Ri). When no drug (D) is present, a constitutive basal signal output (the existing physiological or biochemical response) is more or less high depending on the actual Ra/Ri ratio. Drug binding to R may shift the equilibrium in either direction. The extent to which the equilibrium is shifted towards Ra or Ri is determined by the relative affinity of the drug for the two conformational states. A drug with a higher affinity for Ra than for Ri will drive the equilibrium to Ra and thereby activate the receptor. Such a drug is called an agonist and a full agonist is a drug selective enough regarding Ra to drive all the receptor in its active state and get a maximal response. When a drug has only a moderately greater affinity for Ra than for Ri, its effect will be lower than for a full agonist and such a drug is termed a partial agonist because it cannot produce a full effect. A drug that binds Ra and Ri with equal affinity will not alter the equilibrium between Ra and Ri, will have no net effect of its own, and will act as a competitive antagonist. Finally, a drug with a higher affinity for Ri than for Ra will shift the equilibrium towards Ri and will produce an effect opposite to that of an agonist and is termed an inverse agonist. For example, cimetidine and ranitidine are inverse agonists of H_2-receptors. Under conditions where the conformational equilibrium of the unliganted receptors is strongly in favor of Ri (i.e., no constitutional spontaneous activity), the model is operationally equivalent to the graded model.

equilibrium. It is the conformational change (i.e., isomerization) of the receptors from an inactive to active state that initiates the pharmacological response. This spontaneous equilibrium may be shifted by the binding of ligands to the receptor. For example, the GABA–benzodiazepine receptor exists in two conformations, an active open channel conformation with high affinity for GABA, and an inactive closed conformation with low affinity for GABA. The two forms are in equilibrium. In this scheme diazepam (an agonist) shows high affinity for the active conformation stabilizing the binding of GABA to the activated conformation. The inactive conformation would be favored in the presence of inverse agonists.

In the framework of this model, an agonist is a ligand that preferentially binds to the active state of the receptor and thus shifts the equilibrium in the direction of the active state. A full agonist is selective for the active form whereas a partial agonist has only a slightly higher affinity for the active receptor than for the inactive form. An inverse agonist is a ligand for which a response may be observed only if there is a preexisting level of receptor activity, as with $GABA_A$ receptors. The two main sources of tone result from either the presence of endogenous ligand or from constitutive receptor activity. These active receptors display a basal effect even if there are no agonist ligands binding to them. A decrease in physiological or biochemical response may be observed if an inverse agonist with a preference for the inactive receptor is added.

In the framework of this biologically based theory, the classical receptor theory has to be revisited. For instance, the measured Kd no longer represents the affinity for either active or inactive receptor but lies in between and Kd is a function of both affinity and efficacy (for details see Rang, 2006). Many compounds previously identified as antagonists appear to act as (partial) inverse agonists, that is they actually diminish the constitutive activity of the receptor. This is the case for cimetidine, which was previously considered an H_2 antagonist. Although the therapeutic relevance of inverse agonists needs to be confirmed, the ligand of choice may be an inverse agonist for some receptors with high constitutional activity. Finally, the last type of ligand to be considered in the two-state model paradigm is the neutral competitive antagonist that has equal affinity for both conformations and does not affect the equilibrium.

The two-state model has given rise to more advanced models such as the ternary complex model or the extended ternary complex model to take into account our knowledge of the signal transduction associated with G-protein-coupled receptors.

Currently, our concepts are still evolving and new descriptive terms such as functional selectivity, agonist-directed trafficking, biased agonism, protean agonism, etc. are being introduced to explain what were previously viewed as artifacts (see Urban et al., 2007; Kenakin, 2008).

Down- and Up-Regulation

The effect of a drug often diminishes when it is given repeatedly. The term used to describe a gradual decrease in responsiveness to chronic drug administration (days, months) is *tolerance*. *Tachyphylaxis* is an acute form of tolerance. Several pharmacodynamic mechanisms (desensitization, loss of receptor, exhaustion of mediator, etc.) and pharmacokinetic mechanisms (metabolism induction, active extrusion of the drug, etc.) may explain tachyphylaxis and tolerance. For loop diuretics such as furosemide, it was observed during a chronic treatment a progressive diminution of maximal natriuretic effect. This tolerance phenomenon is known for diuretics as the *braking phenomenon* and results from activation of the renin–angiotensin–aldosterone system and sympathetic nervous system.

Chronic stimulation of receptors with a drug results in a state of long-term desensitization, also termed *down-regulation*. This is often due to a decrease in the number of receptors, whereas under-stimulation leads to *up-regulation* due to an increase in the number of receptors and a functional supersensitivity. Receptor expression is a dynamic process with equilibrium between the synthesis and destruction of receptors. For example, the binding of a hormone such as insulin to its receptors on the surface of a cell initiates endocytosis of the hormone–receptor complex and its destruction by intracellular lysosomal enzymes. This internalization regulates the number of sites that are available for binding on the cell surface. Although receptor desensitization is generally an unwanted effect, it can provide a way of controlling certain physiological systems. For example, long-term contraception by means of gonadotropin releasing hormone (GnRH) agonist-induced down-regulation of pituitary secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), as deslorelin acetate is now used in dogs and cats. The advantage of this nonsurgical method is its reversibility when the treatment is discontinued.

From the Pharmacological Target to the Animal and Population Pharmacodynamics

Drug *action*(s) (e.g., inhibition of cyclooxygenase) will lead to a pharmacological *effect* (e.g., inhibition of prostaglandin synthesis), which in turn leads to the expected clinical *response* (e.g., reduction of inflammation) and finally to the ultimate clinical outcome (cure or not cure). Drug action, drug effect, clinical response, and the final drug *effectiveness* at the population level are the four main levels of pharmacodynamic description. The clinical response of interest depends on many factors beyond the simple drug action at the enzyme or receptor level. Drug response will be influenced by physiological factors (age, sex, body weight, social behavior, etc.), the genetic background of the animal (breed, strains, etc.), with a possible variability due to polymorphism (see Chapter 50), the disease and its progression (fever, anorexia, etc.), and the treatment itself (previous drug administration, cotreatments, etc.). This explains why the response can vary significantly between animals and, for a given animal, between occasions, making the rational development of a dosage regimen difficult. A dose–effect relationship holds for all drugs, and the goal for determination of a rational dosage regimen is first of a pharmacodynamics nature to specify the range of efficacious plasma concentrations. Indeed, it is a tenet of pharmacology that the plasma concentration is the driving force controlling the biophase concentration and, in equilibrium conditions, the free plasma concentration should be equal, or at least proportional to, the free biophase concentration where receptors and enzymes are located.

The concept of a *therapeutic window* has been coined to describe this range of useful plasma concentrations, in which the expected clinical response is obtained with a minimal risk of adverse effect. The therapeutic window is the optimal range of drug exposure between a low minimally effective concentration and a high toxic concentration. For some drugs the therapeutic window is rather narrow (as for digoxin, bromide, phenobarbital, gentamicin, etc.) requiring possible *therapeutic drug monitoring* to ensure treatment with a reasonable margin of safety. For other drugs, the therapeutic window is large, allowing much more flexibility for the design of a dosage regimen, and these are the only possible drugs suitable for collective treatment or routine prevention (as for most antibiotics and antiparasitic drugs). A concept related to therapeutic window is the *therapeutic index,* which attempts to reflect with a single figure ratio the margin between useful and toxic dose.

An Overview on the Determination of an Effective and Safe Dosage Regimen

The determination of a safe and effective dose or dosing regimen (i.e., dose and dosage interval) is essential for an appropriate exposure of receptors and optimal use of drugs. Dose–response analysis consists of using appropriate scientific tools to answer the following questions (Ruberg, 1995): (i) Is there any drug effect? (ii) Which doses exhibit a different response to the control? (iii) What is the nature (shape) of the dose–response relationship? and finally (iv) What is the optimal dose? In addition, an optimal dosage regimen in veterinary medicine must not only be safe and effective when administered to a single animal in well-controlled conditions but also when administered collectively to food-producing animals. It also needs to be optimized to avoid any public health concerns regarding the questions of drug residues, pollution of the environment, or antimicrobial drug resistance.

Various scientific tools are available to answer these different questions, and the choice of a given approach will be dictated by the therapeutic area, the phase of drug development, the availability or not of surrogate endpoints with good metrological properties, and the ease with which the clinically relevant outcomes can be assessed.

In veterinary medicine the most well-established approach is the so-called dose titration trial. This consists of testing different dose levels and selecting the one that achieves some preestablished regulatory requirement in terms of cure rate (as for antiparasitic drugs).

Although this dose titration approach has its attractions, it also has limitations and these led to the investigation of alternatives such as the PK/PD approach. The plasma concentration profile is generally the driving force controlling the time course of drug concentration at the site of action (the biophase for systemically acting drugs). This led to integration of the PK and PD information by means of a link model, and production of a versatile tool that could be used to determine the optimal dosage regimen. In PK/PD, the variable selected to explore the dose–effect relationship is the plasma concentration profile (not the nominal administered dose).

PK/PD modeling enables the numerical values of the three key PD parameters characterizing any drug, namely its maximal efficacy (E_{max}), potency (EC_{50}), and sensitivity, to be estimated in vivo. The sensitivity is assessed from the slope of the concentration–effect relationship and is a major determinant of the drug's selectivity (see Figure 4.5). Once these different PD parameters have been established, the dose–effect relationship and the time-to-effect relationships corresponding to different possible PK profiles can easily be explored by simulations to predict the time course of drug effects under different physiological and pathological conditions. These different scenarios may then be given to clinicians to assist them in designing future confirmatory clinical trials.

Designs for Dose Titration and the Determination of an Effective Dose

The selection of a dose should be based on well-controlled studies and use accepted statistical methodology. A simple parallel design is often selected in veterinary medicine. In this case the animals (healthy, spontaneously or experimentally infected or infested, etc.) are randomly allocated to a few predetermined dose groups (often including a placebo, low dose, medium dose, and

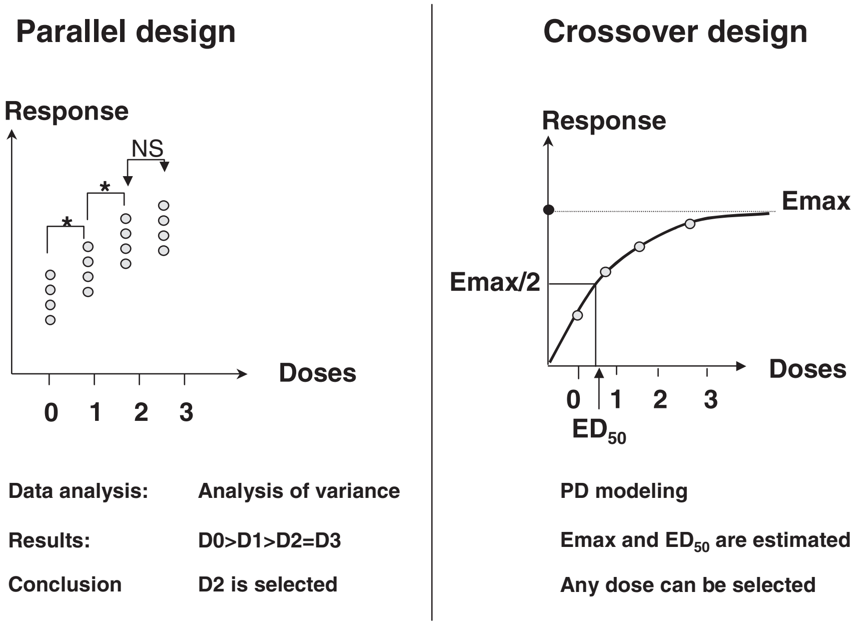

Figure 4.10 Parallel versus crossover design for a dose-titration study. In a parallel design the animals (here n = 4 per group) are randomly assigned to one of the tested doses (0, 1, 2, or 3). Data analysis is performed by a test of the hypothesis (ANOVA), the selected dose being one of the tested doses (no interpolation). Here D2 would be selected because it gives a significantly higher response (∗) than D1 but is not significantly (NS) different from D3. In a crossover design, all the animals receive all the tested doses and individual dose–effect curves are generated. For each individual curve, PD parameters (E_{max}, ED_{50}) can be computed and any dose over the tested range can be selected. With a crossover design, but not in a parallel design, information is obtained about the shape of the dose–response relationship and on variability within the population.

high dose, i.e., four dose levels) and the endpoints of interest are compared using an appropriate statistical test of the hypothesis (Figure 4.10). The parallel design has the advantage of being straightforward in design and analysis but has several serious limits. Since each subject receives only one dose level, it provides only a group mean (population average) dose response, not an individual dose response. This design leads to biased parameter estimates, poor or no estimates of variability, and is unable to provide information on the shape of the individual dose–response relationship (Verotta et al., 1989), which is needed to determine drug selectivity. More importantly, the dose selected as the most effective dose is unlikely to be the optimal dose. The selected dose is obliged to be one of the tested doses and is highly dependent on the power of the experiment's design (number of tested animals), so that trials with a small sample size generally lead to the selection of an excessively high dose.

The parallel design is used in studies of antiparasitic and antimicrobial drugs as the pivotal outcome is eradication of the pathogen (an irreversible drug effect). In contrast, drugs acting on physiological systems (e.g., cardiovascular, nervous system, kidney, etc.) almost invariably act reversibly so that a crossover design becomes possible.

In a crossover design each animal is tested with a range of dose levels so that individual dose–response curves are generated. So long as the number of tested doses is sufficient, the dose–effect relationship for a given animal can then be modeled using a classical sigmoidal relationship of the form:

$$Effect = E_0 \pm \frac{E\max \times Dose^n}{ED_{50}^n + Dose^n} \tag{4.4}$$

where *Effect* (dependent variable) is the predicted effect of a given dose (independent variable) and E_0 the effect without the drug (i.e., a placebo effect or the base line response of the system). E_{max} is the maximum possible effect and ED_{50} is the dose producing half E_{max}. E_{max} is a measure of the drug (physiological) efficacy whereas ED_{50} is a measure of the drug potency (Figure 4.10). It should be stressed that although the two terms efficacy and potency are often confused and used interchangeably within scientific and pharmaceutical communities, the most potent drug may not always offer the most clinically effective dose (see Figure 4.6).

When an exponent (*n*) is included in the model, it reflects the slope of the dose–effect relationship and can provide information about drug selectivity for the tested effect (Figure 4.11).

This relationship can then be used to define the minimum effective dose, the maximum effective dose, and the maximum tolerated dose. The fundamental difference between parallel and crossover designs is that with a crossover design, any dose within the range of doses tested can be selected as the optimal dose because interpolation is possible, whereas this is not the case for a parallel design (see Sheiner et al., 1991 for details).

The Difference Between Dose Titration and the PK/PD Modeling Approach in Determining a Dose

It should be noted that in the following equation, ED_{50} is not a true PD parameter but a hybrid PK/PD variable. In fact ED_{50} is the product of three separate determinants, as indicated by the following relationship:

$$ED_{50} = \frac{Clearance \times EC_{50}}{Bioavailability} \tag{4.5}$$

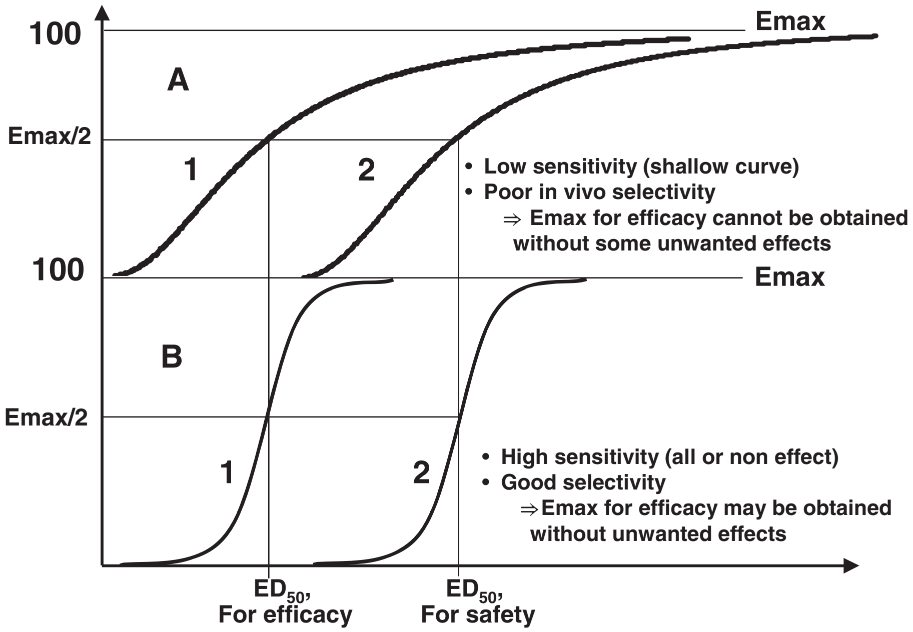

Figure 4.11 In vivo drug selectivity is related to both the therapeutic index (i.e., the ratio $ED_{50,safety}/ED_{50,efficacy}$) and to the slope of the concentration effect relationship. Drugs A (top) and B (bottom) have the same potency (ED_{50}) and the same efficacy (same E_{max}) for the desired effect (curve 1) and unwanted effects (curve 2), that is the same therapeutic index. However, they differ in terms of sensitivity (slope) (shallow for drug A and steep for drug B). Only with drug B, can the full effect (i.e., E_{max}) be obtained without any significant side effect despite the fact that drugs A and B have the same $ED_{50,safety}/ED_{50,efficacy}$ ratio. Definition of therapeutic index by $ED_{10,safety}/ED_{90,efficacy}$ takes into account the differences in sensitivity of dose–response curves.

where *Clearance* is the plasma clearance, *Bioavailability* is the extent of the systemic bioavailability (for the extravascular route of drug administration) and EC_{50} is the plasma concentration providing half E_{max}.

Figure 4.1 illustrates the fundamental differences between a dose-ranging trial and a PK/PD trial. Both aim at documenting the same relationship between dose and drug response but in a PK/PD analysis, the effect is explained by replacing dose with the plasma concentration profile so that the estimated drug potency is expressed as an EC_{50}, not an ED_{50}. The EC_{50}, unlike ED_{50}, is a true PD parameter. There is only one EC_{50} for a given endpoint and this EC_{50} value is not influenced by PK parameters, administration route, or formulation. This means that if a new formulation of the drug is to be developed, there is no need to run a new PK/PD trial. All that is required is a PK study to establish the influence of the new bioavailability on the effect. Hence, EC_{50} has a much wider application than ED_{50}, and the determination of EC_{50} is a primary objective of PK/PD studies. Furthermore, because the plasma concentration–time data include temporal information, PK/PD modeling is appropriate not only for establishing a suitable dose but also the dosage interval.

Building PK/PD Models

In general, three different models are considered when building a PK/PD model: a PK model transforming the dose into a concentration versus time profile, a link model describing transfer of the drug from the plasma into the biophase, and a PD model relating the biophase concentration to an effect (Holford and Sheiner, 1981).

The PK model is generally a traditional compartmental model and the PK parameters are estimated in the conventional way. The PK model is used to provide concentration data for the PD model.

The plasma concentration profile and the effects are usually not in phase, and plasma concentration cannot directly be incorporated into a PD model. The effect of most drugs lags behind the plasma concentration. This can easily be visualized by plotting the effects (Y axis) against plasma concentrations (X axis). A loop is observed when the data points are in chronological order. This is known as a *hysteresis loop* from the Greek word meaning “coming late” (Figure 4.12). When a hysteresis loop is observed, the cause of the delay must be identified to select the appropriate modeling strategy. When the delay is of PK origin (e.g., slow rate of drug distribution at the biophase, etc.), and when the drug effect is directly related to the drug concentration at the biophase level, a so-called *effect compartment model* can be chosen. A link model is interposed between the PK and PD model to account for the delay. Generally, this consists of describing drug transfer into the biophase by a first order rate constant, which is the parameter of the link model. The first-order rate constant (generally denoted as K_{e0}) can be estimated from the time course of the drug effect (see Holford and Sheiner, 1981 for details).

For most drugs, the combination of drug with its receptor is followed by a cascade of time-dependent biochemical, physiological, and/or pathophysiological events (see Figure 4.8). Thus the delay between plasma concentration and the response is due to the intrinsic temporal responsiveness of the system. Indirect response models are used for this type of response.

Four basic indirect response models have been proposed (Dayneka et al., 1993), based on Equation 4.6,

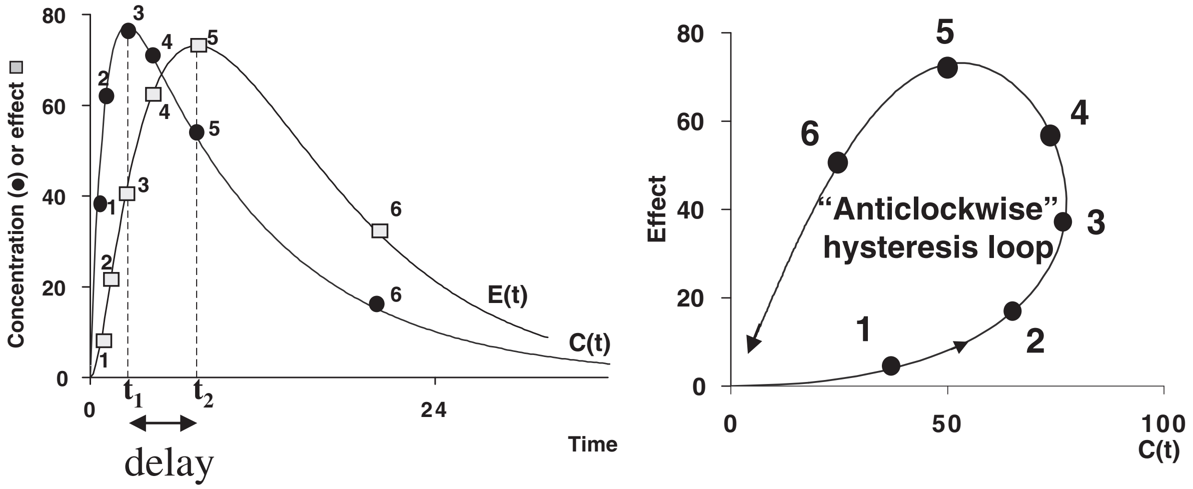

Figure 4.12 In general, plasma concentration time and effect time relationships are not in phase. The peak concentration occurs at time t_1 and peak effect occurs at a later time t_2. An arithmetic plot of effect versus time reveals a hysteresis loop. For any given concentration, two different levels of effect are possible.

which describes the rate of change of response over time with no drug present:

$$\frac{dR}{dt} = K_{in} - K_{out}R \tag{4.6}$$

where *dR/dt* represents the rate of variation in the response variable (R). The model assumes that the measured response is being formed at a constant rate (K_{in}) but disappears in a first-order manner (K_{out}). For the variation in body temperature (°C) during fever, K_{in} (°C per time unit) reflects the level of the thermogenesis and K_{out} (per time unit) expresses the rate of thermolysis. It can then be assumed that the indirect drug action consists of inhibiting or stimulating physiological factors that control production or dissipation of the measured effect, described as:

$$\begin{aligned}\frac{dR}{dt} &= K_{in} \times \{\text{stimulation or inhibition function}\} - K_{out} \\ &\quad \times \{\text{stimulation or inhibition function}\} \times R \end{aligned} \tag{4.7}$$

where the *stimulation or inhibition function* can be the classical $E_{\max}$ model.

The final model to consider in the PK/PD modeling approach is the PD model. There are two main types of PD models, describing either a *graded* concentration–effect relationship or a *quantal* concentration–response relationship. A graded model is used when the response to different drug concentrations can be quantified on a scale (e.g., body temperature, survival time). On the other hand, in a quantal model (also known as a fixed-effect model), the described effects are nominal (categorical) (e.g., dead or alive, cured of parasites or not, appearance of unwanted effects or not). The dose or exposure in quantal dose–response (or exposure–response) relationships is not related to the intensity of the effect but to the frequency of an all-or-none effect. Quantal responses are often clinical endpoint outcomes, whereas graded responses are often surrogates.

The most general model for a graded effect relationship is the Hill model, also known as the sigmoidal $E_{\max}$ model:

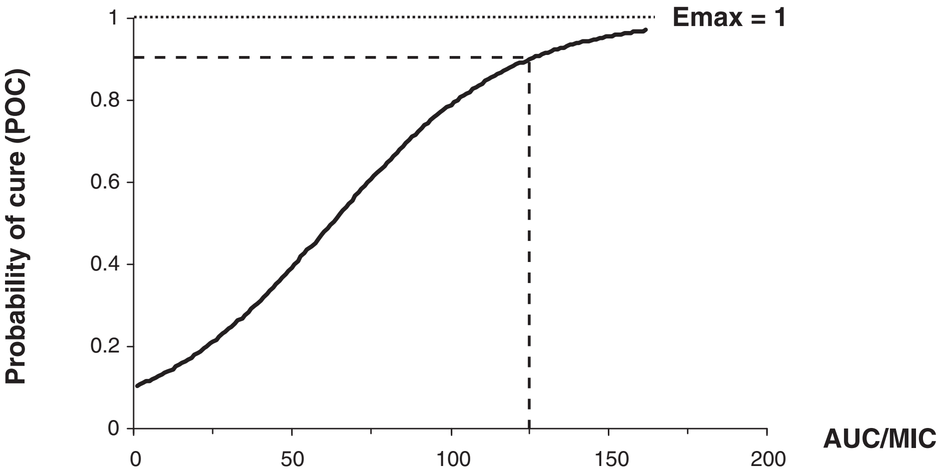
$$E(t) = E_0 \pm \frac{E\max \times C^n(t)}{EC_{50}^n + C^n(t)} \tag{4.8}$$

where *E(t)* is the effect observed for a given concentration at time t (*C(t)*), $E_{\max}$ is the maximal effect attributable to the drug, EC_{50} is the plasma concentration producing 50% of $E_{\max}$, and n is the Hill coefficient, representing the slope of the concentration–effect relationship. When $n = 1$, the Hill model reduces to the $E_{\max}$ model, which corresponds to a hyperbolic function. Many drug effects involve the modulation of a physiological variable (e.g., blood pressure). In this case, inclusion of the term E_0 in Equation 4.8 indicates the presence of a baseline effect. E_0 can also represent a placebo effect.

When the drug effect corresponds to the inhibition of a biological process, the drug effect is subtracted from the baseline (E_0) and EC_{50} is often expressed as an IC_{50}, that is the concentration producing 50% of the maximum inhibition effect ($E_{\max}$). For other PD models see Holford and Sheiner, 1981.

Equation 4.8 contains several parameters (E_0, $E_{\max}$, EC_{50} or IC_{50}, and n). The ultimate goal of PK/PD modeling is to evaluate the means and variances of these parameters from the in vivo observations of *E(t)* obtained over a range of *C(t)* values.

In a graded concentration response relationship, that is when the outcome is binary (e.g., cure or no cure, appearance or no appearance of an adverse effect) or when the



$$POC = \frac{1}{1+e^{2.19-0.03509\times(AUC/MIC)}}$$

Figure 4.13 Logistic regression. When an effect is binary (cure / no cure), a logistic curve is used to describe the relationship between the independent variable (often dose, exposure, or any explicative variable) and the dependent variable (a probability between 0 and 1). This quantal dose–response curve does not relate dose to intensity of effect but to the frequency in a population of individuals in which a drug produces an all or nothing effect. Here, the probability of cure (POC) for a hypothetical concentration-dependent antibiotic has been plotted against the value of a PK/PD index generally selected for this class of antibiotics (i.e., AUC/MIC). The value 2.19 yields P = 0.1 when X is zero (placebo effect) and b = 0.035 gives the "sensitivity," that is the slope of the response. Here, for an AUC/MIC of 125 h, the POC is 0.9 (90%).

results of the drug effect are provided as scores (responder/ nonresponder) the link between the measure of drug concentration exposure and the corresponding probability is given by a logistic equation of the form:

$$P = \frac{1}{1+e^{-(a+bX)}} \tag{4.9}$$

where P is the probability (e.g., of cure from 0 to 1), a is a parameter for baseline (e.g., a placebo effect) and b is an index of sensitivity (similar to a slope), X is the independent variable and may be the exposure (rather than the instantaneous concentration) or a quantitative index predicting efficacy (ex. AUC/MIC for a concentration-dependent antibiotic). Figure 4.13 shows a logistic curve for the probability of cure of an antibiotic. In logistic regression, the dependent variable is termed a *logit*, which is the natural log of the odds, that is:

$$\log(odds) = \text{logit}(P) = Ln\frac{P}{(1-P)} \quad \text{and} \quad odds = \frac{P}{1-P} \tag{4.10}$$

Selection of the Dose and Dosage Regimen

The next step, after estimating all the relevant PD parameters, is to select a dose level and a dosage interval. When the PD parameters have been estimated with a direct effect model and the investigated endpoint has a clinical meaning, Equation 4.5 can be used directly. Often, in the case of NSAIDs, a dose that is close to the ED_{50} is selected and this can easily be computed by incorporating the corresponding EC_{50} into Equation 4.5. For example, in the horse, the estimated potency of phenylbutazone, determined from its effects on stride length in an experimental carpitis, indicated an EC_{50} of 3.6 μg/ml (Toutain et al., 1994). As the plasma clearance of phenylbutazone in horse is 991 ml/kg/day, the calculated dose required to achieve half the maximal effect is 3.6 mg/kg/day. This is slightly below the manufacturer's recommended daily dosage of 4.4 mg/kg. However, if the investigated endpoint for an NSAID is the PGE_2 inhibition, that is a biochemical surrogate, the EC to incorporate into Equation 4.5 may differ from the EC_{50}. It has been shown that at least 90–95% of the magnitude of COX-2 inhibition is clinically relevant. In this case, it is an EC_{95} that should be incorporated in Equation 4.5. In calves treated with tolfenamic acid, for instance, 95% PGE_2 inhibition is obtained with a plasma concentration of 0.245 μg/ml. When this EC_{95} is incorporated into Equation 4.5 together with the plasma clearance of tolfenamic acid in calves (7.2 l/kg/day), a dose of 1.76 mg/kg/24 h is obtained. This is approximately equal to the manufacturer's recommended daily dose of 2 mg/kg.

When the PD parameters have been established using an indirect effect model, the relationship between the

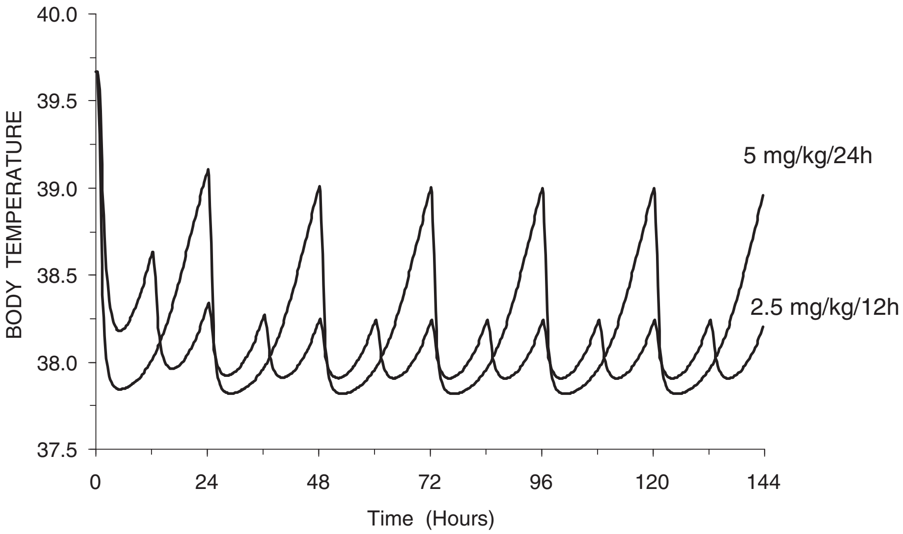


Figure 4.14 Plot of predicted body temperature (°C) versus time (h) after administration of nimesulide in dogs at two different dosage regimens (2.5 mg/kg/12 h and 5 mg/kg/24 h, for 6 consecutive days). Visual inspection of the figure suggests the superiority of the 2.5 mg/kg/12 h dosage regimen. *Source:* Toutain et al., 2001a. Reproduced with permission of John Wiley & Sons, Inc.

clinical response and the EC_{50} is not straightforward. This is also true when the goal is to select the optimal dosage regime to achieve a particular plasma concentration profile (e.g., to maintain plasma concentrations above the MIC for a time-dependent antibiotic) or to determine the most appropriate time interval between two administrations (i.e., to optimize efficacy while minimizing unwanted side effects). In these cases the best approach is to perform simulations. The PK/PD model can be used to simulate a large number of dose and dosage interval scenarios and screen for those dosage regimens with the best efficiency or safety margins. Such analysis requires no additional time or cost during drug development. For example, it was shown for nimesulide in dogs that a PK/PD model predicted a better antipyretic efficacy for nimesulide at a dosage regimen of 2.5 mg/kg twice a day rather than at 5 mg/kg per day, although both dosage regimens were equivalent in terms of lameness suppression (Toutain et al., 2001a) (Figure 4.14).

The PK/PD approach may also be used to determine an optimal dosage regimen for antibiotics. The objectives of rational antibiotic therapy are dual, that is optimization of clinical efficacy and minimization of the selection and spread of resistant pathogens (Lees and Aliabadi, 2002; Toutain et al., 2002). The poor sensitivity of clinical outcomes in indicating the best dosage regimen in terms of bacteriological cure, has prompted investigation of the value of PK/PD surrogate indexes to establish an optimal dosage for antibiotics. Three PK/PD indices appear to be sufficient to predict antibiotic effectiveness: the *f*AUC/MIC ratio, an index used for quinolones; the fC_{max}/MIC ratio (where C_{max} is the maximum free plasma concentration), an index selected for aminoglycosides; and *f*T>MIC (the time during which free plasma concentrations exceed MIC, expressed as a percentage of the dosage interval), an index selected for the so-called time-dependent antibiotics such as β-lactams. All three indices are surrogate markers of what is ultimately expected, that is clinical recovery and bacterial eradication.

It should be noted that these PK/PD predictive indices of in vivo efficacy are built on free (*f or fu*) plasma antibiotic concentrations and not on total plasma concentration or total tissue antibiotic level. Indeed, most pathogens of clinical interest are located extracellularly and the biophase for antibiotics is the extracellular fluid.

Once a PK/PD surrogate index has been selected, its breakpoint values (critical values) need to be considered in relation to the clinical objectives. For quinolones, it is generally reported that the plasma concentration should be five times higher than the limiting MIC (generally the MIC_{90}, i.e., the MIC covering 90% of the bacterial population). This is equivalent to saying that the PK/PD breakpoint, for the index predictive of quinolone efficacy (i.e., AUC/MIC) calculated over 24 h, should be 125 h.

Taking the example of a quinolone, the expected daily dose can easily be computed as:

$$\textit{Daily dose}\text{ for a quinolone} = \frac{\text{Plasma clearance} \times \left(\dfrac{AUC}{MIC}\right)\text{breakpoint value} \times MIC_{90}}{fu \times \text{Bioavailability}} \tag{4.11}$$

where *fu* is the free fraction. The (*AUC/MIC)* breakpoint value in Equation 4.11 is, for example, 125 h and, in this case, the plasma clearance of the quinolone under investigation should be expressed per hour (not per day) if the daily dose has to be computed. Simplified, the daily

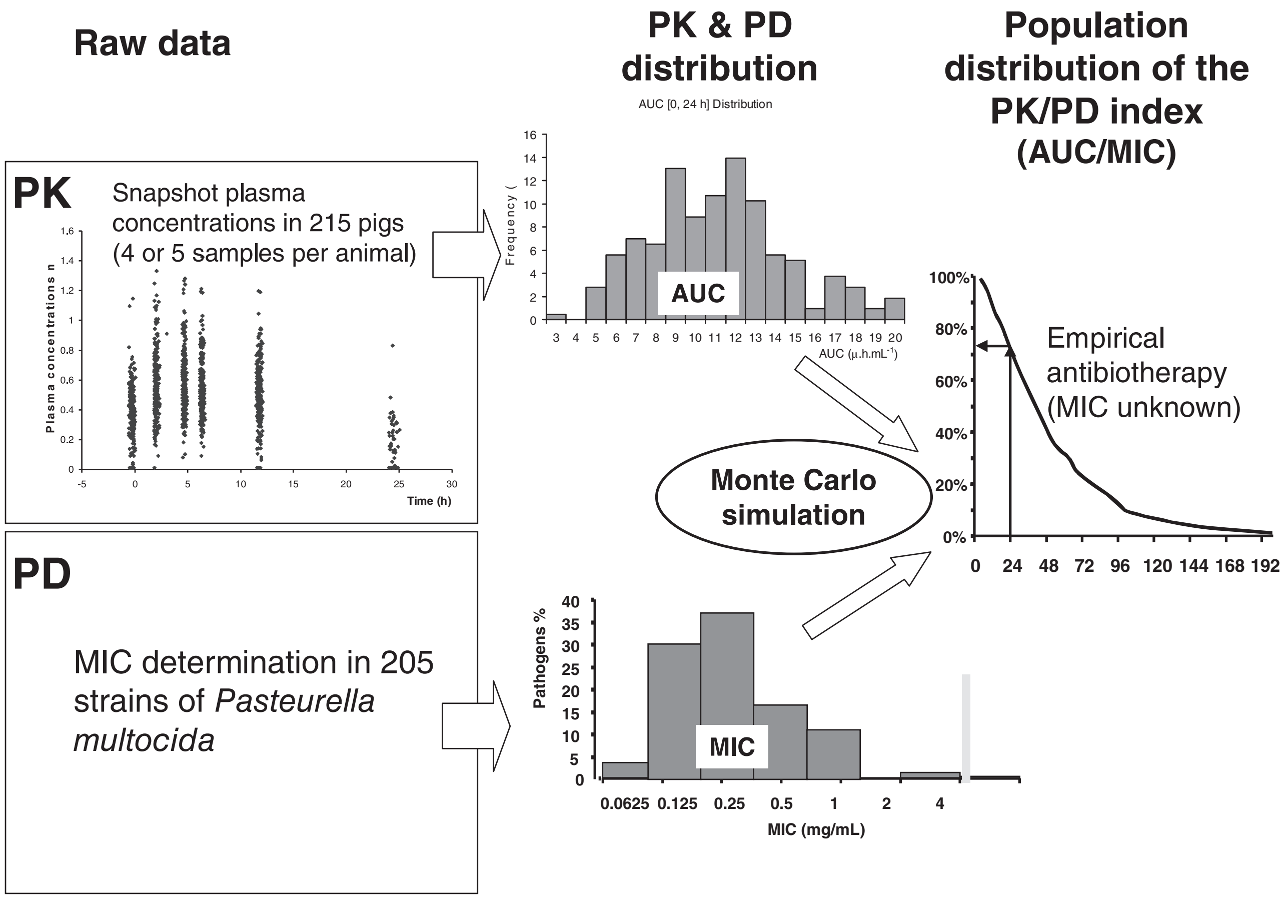

Figure 4.15 Monte Carlo simulation and the PK/PD index population distribution for doxycycline in pigs.
Left top panel: plasma concentrations of doxycycline were measured in 215 pigs under field conditions (4 or 5 samples per pig) after metaphylactic treatment by oral route. The plasma concentrations were obtained with a second doxycycline dose of 5 mg/kg administered approximately 14 h after an initial 5 mg/kg dose.
Left bottom panel: minimum inhibitory concentration (MIC) was determined in 205 strains of *Pasteurella multocida*.
Middle panel: exposure distribution as AUC (0–24 h) and the MIC distribution. These two distributions were used for Monte Carlo simulations. The application of Monte Carlo simulation accounts in a balanced manner for variability in drug exposure (AUC) as well as pathogen susceptibility data (MIC distribution) to establish the population distribution of the relevant PK/PD index (AUC/MIC).
Right panel: the curve gives the percentage of pigs in a population attaining a given value of the PK/PD predictor (AUC/MIC). The curve was generated for an empirical antibiotherapy (MIC distribution known, but MIC for the involved pathogen unknown) based on an administered dose of doxycycline of 10 mg/kg, that is the recommended daily dose regimen. Visual inspection of the curve indicates that a PK/PD index of 24 h (i.e., a daily mean plasma concentration equal to the corresponding MIC) would be attained in 72% of the pigs with an empirical antibiotherapy. If it is assumed that only the free drug is active, the achieved breakpoint should be divided by approximately 10, as the extent of plasma protein binding for doxycycline is about 90%.

dose can be computed using the following equation, which is actually Equation 4.11 with EC_{50} equated to $5 \times MIC_{90}$:

$$\textit{Daily dose} \text{ for a quinolone} = \frac{\text{Plasma clearance} \times 5 \times MIC_{90}}{fu \times \text{Bioavailability}} \tag{4.12}$$

Here, plasma clearance is the daily clearance and 5 the scale factor equivalent to the breakpoint value of 125 h (5 is the round-up of 125 h/24 h) and by which the MIC_{90} should be multiplied to guarantee an appropriate efficacy (for further explanation of Equations 4.11 and 4.12, see Toutain, 2003 and Toutain et al., 2007).

Population PK/PD

One important advance has been to separate the two main sources (PK and PD) of variability through the use of population PK/PD approaches. In this way, population analysis can explain, with some covariates, the variation between animals (or groups of animals) not only in terms of drug exposure but also in terms of drug responsiveness. This is especially true in the case of antibiotics, where clinical response is affected not only by the ability of the drug to reach the site of infection but also by the PD variability (host response to the invading pathogen and bacterial susceptibility). In the case of antibiotics, if both the PK and PD (MIC) variabilities are known from relevant population investigations, the statistical distribution of the selected PK/PD index that is predictive of clinical efficacy can readily be established using *Monte Carlo simulations*. Monte Carlo is a term applied to a numerical method with a built-in random process. It involves combining the variability of antimicrobial drug exposure with the variability in pathogen susceptibility according to the corresponding probability density functions. With Monte Carlo simulations, a large hypothetical population of animals (or outcomes) may be generated to determine the probability of attaining a given PK/PD breakpoint in a given proportion of the population (Figure 4.15). This allows selection of a dosage regimen based on attaining the recommended PK/PD target breakpoint in most animals. For more details see Lees et al. (2006) and, for an example, the case of tulathromycin in the calf (Toutain et al., 2017).

Limits of the PK/PD Modeling Approach for a Dose Determination: Clinical Response versus Surrogate

Very often the drug response of interest is difficult to obtain (e.g., bacterial cure for an antibiotic), difficult to measure quantitatively (e.g., demeanor for a tranquilizer), or delayed in time (e.g., survival time for cancer therapy). Under these conditions, the effect of ultimate interest in a PK/PD trial may be replaced by a surrogate endpoint, that is a biomarker that is objectively measured and validated as an indicator of a normal or a pathological process (Anonymous, 2001; Colburn, 2000). Some examples of surrogates in veterinary medicine are the PK/PD indices that have been proposed for predicting clinical success and bacteriological cure for antibiotics. Angiotensin converting enzyme (ACE) inhibition is used as a surrogate to evaluate ACE inhibitors, although it should be kept in mind that the ultimate goal of therapy with ACE inhibitors is to increase the survival time of diseased animals and the quality of their lives, and not to inhibit an enzymatic activity. Indeed, a drug may have a favorable effect on a biomarker and an unfavorable effect on the disease and any biomarker believed to be a surrogate of clinical relevance needs to be validated. The CAST trial in human medicine is an appropriate illustration (Ruskin, 1989). It was initially thought that pharmacological suppression of premature ventricular contraction (PVCs), identified by postmyocardial infarct monitoring, could reduce the incidence of subsequent arrhythmias. The abilities of different antiarrhythmic drugs to prevent cardiac death (class I antiarrhythmic) were tested against a placebo. It was finally shown that drug therapy was not only associated with a reduction of PVC but also with an increase in the incidence of arrhythmic deaths. This trial illustrates that any surrogate needs to be validated for its clinical relevance even when it has a strong mechanistic link with the condition under treatment.

Conclusion

A drug action is first expressed at a target site (receptor, enzyme, transporter, etc.) where it produces a biochemical or a cellular event such as enzyme inhibition or depolarization. This primary drug action then leads rapidly to some physiological and observable changes such as smooth muscle contraction, a decrease of blood pressure, or an inhibition or stimulation of the secretion of an endogenous substance. This is the primary drug effect. Ultimately these short-time effects are collectively responsible for the delayed overall clinical response such as the survival time or the well-being of the animal. In this context, PK/PD approaches are able to bridge in vitro and in vivo situations, that is to predict the time-development of a drug effect from an in vitro drug action. PK/PD is a tool that is mainly used to select rational dosage regimens (dose, dosing interval) for pivotal confirmatory clinical testing. In PK/PD modeling, the plasma concentration profile (not the dose) plays the role of explicative variable for the effect. Because it separates the two main sources of interspecies variability (PK/PD) it is well suited to multiple-species drug development and interspecies extrapolation. The PK/PD approach offers many advantages over a classical dose titration, especially the possibility of determining a dosage regimen by testing only a single dose. The main limitation of the PK/PD approach is that surrogate biomarkers are used to judge efficacy, that is various drug effects rather than the overall clinical response, the risk being determination of a dose that is effective against the biomarker but does not improve the disease. This is particularly true in chronic disease where the clinical outcome may take months or years to occur.

Principles of Pharmaceutics and Veterinary Dosage Forms

Raafat M. Fahmy and Marilyn N. Martinez

Introduction

Pharmaceutics is an interdisciplinary science that involves the integration of physical pharmacy, pharmaceutical formulation, manufacturing technology, dispensing pharmacy, and the laws of pharmaceutics. Irrespective of whether a drug product is intended for use in humans or veterinary species, the same factors influence the process of dosage form development and quality control considerations. Many of these concepts were introduced in Chapters 2 and 3 of this text and will be expanded upon here to give a perspective on how dosage forms influence drug disposition and activity. These factors include:

- The physical and chemical characteristics of the active pharmaceutical ingredient (API) such as:
  - intrinsic solubility (aqueous solubility of the unionized form of the drug);
  - pKa;
  - ability to traverse the biological membrane;
  - stability:
    - in the presence of excipients
    - during manufacture
    - shelf life
  - crystal characteristics (e.g., crystalline habit, particle size, particle shape).
- The intended use of the dosage form:
  - targeted duration of drug release;
  - stability in the gastrointestinal (GI) tract (orally administered products);
  - ease of administration;
  - limitations on dosage form:
    - size of tablets or capsules or volume of an oral liquid
    - injection volume
    - location of administration (e.g., skin, ophthalmic, ear).
- Formulation that includes excipients to insure that the product delivers the drug in a manner defined by the pharmacologist/clinical expert.
- Method of manufacture (based upon drug and intended dosage form characteristics).

The contents of this chapter provide an overview of each of these points with respect to their relationship to drug products approved for veterinary use. To that end, pharmaceutic principles are discussed from the perspective of the design of drug delivery systems (dosage forms), the formulation and manufacturing variables influencing in vivo and in vitro product performance, and the product understanding necessary to assure that the dosage form is effective, safe, and stable. It should be noted that for those readers interested in learning current recommendations for testing methods for assessing drug intrinsic solubility, the USP has published a general chapter (<1236>) on this topic.

The formulation challenges impacting the animal health pharmaceutical industry parallel those encountered during the development of human pharmaceuticals. In addition, the selection of dosage forms and their corresponding formulations reflect the specific needs of the target animal species, potential breed variation that can influence the rate and extent of drug exposure, the variation in body sizes, species feeding habits, logistical challenges associated with product use, cost to the end user (a question of particular concern for products associated with maintaining herd health), environmental safety, animal disease states (and their impact on drug intake or drug pharmacokinetics), and human food safety (for products intended for administration to food producing animals). To accommodate this diverse range of needs, veterinary medications can be manufactured in a variety of forms including:

- tablets, capsules, and oral solutions and suspensions;
- injectable formulations (solutions, suspensions, and a range of sustained-release formulations);

Figure 5.1 Integration of the physical, chemical, and biological properties of an active pharmaceutical ingredient (API).

- medicated powders for administration in drinking water (herd health);
- drenches (a large volume of aqueous suspension or solution containing the API that is pumped into the animal's rumen);
- medicated articles (a formulation intended for administration in feed. The Type A medicated article is regulated by the FDA as a new animal drug product. However, it is administered to the animal only after substantial further dilution with unmedicated feed);
- topical products (which, in addition to products administered to the skin, includes opthalmics, otics, and intramammary formulations);
- transdermal products (applied to the skin but is systemically absorbed);
- transvaginal products (systemic drug absorption achieved by formulating a product with drug release in the urogenital tract and subsequent absorption across the vaginal epithelium);
- rumen bolus (a large tablet designed for administration in ruminants and which can provide either immediate drug release or remain in the rumen for a prolonged duration of time to provide extended drug release).

Understanding the Active Pharmaceutical Ingredient

Irrespective of the dosage form, it is important to understand the physical and chemical properties of an API prior to product development. Most APIs in use today are solid materials (pure chemical compounds of either crystalline or amorphous structure). In the case of biomass products, the production of the API and related fermentation products need to be carefully controlled.

The purity of the chemical substance is essential for its identification and for determining its chemical, physical, and biological properties. API physicochemical properties may include rheology, particle size, crystalline structure, melting point, and intrinsic solubility, solid-state properties, partition coefficient, pKa, stability, and ionization constant(s) (the extent to which the acid or base ionizes once put into solution). As described in Figure 5.1, integrating our knowledge of the chemical, physical, and biological properties (the latter including the ability of the API to reach its site of action and to generate a biological response) into drug discovery and product development allows for defining the product's Critical Quality Attributes (CQAs) and for formulation optimization.

Physical Properties

Crystalline Form

Many APIs are precipitated during their final stage of synthesis, thereby forming a specific crystalline state. In turn, the crystalline state is a function both of the solvent system used during the initial solubilization process and the conditions of the subsequent drug precipitation. Condition variables of importance include temperature, pressure, rate of cooling, and time. The resulting crystal lattice is comprised of repeating units called unit cells, and all unit cells within a specific crystal are identical (i.e., the same size and arrangement of atoms). Higher levels of energy are required to break strong vs. weak crystal lattices (i.e., characterized by a high melting point). As a result, these more stable crystalline forms typically exhibit low aqueous solubility. Conversely, the amorphous state is characterized by random and irregular positioning of the atoms and a low melting point.

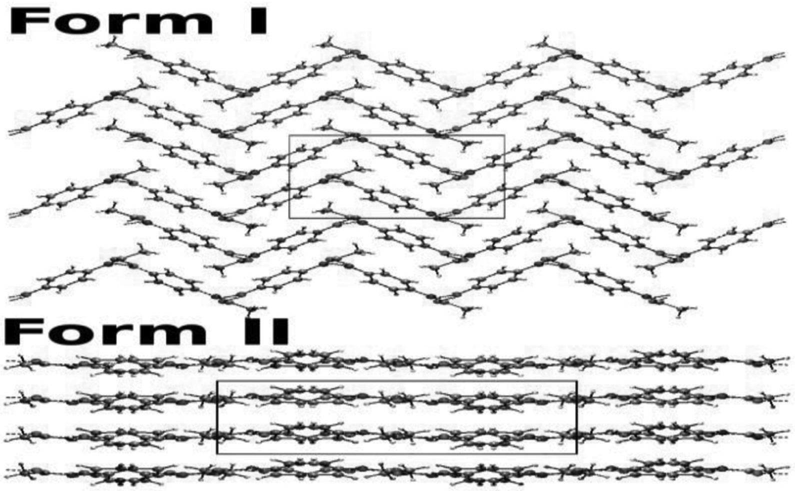

Figure 5.2 An example of two polymorphic forms of the same compound.

An amorphous chemical substance contains no distinct crystalline lattice and therefore is typically the most soluble form of a chemical substance.

Although a low melting point is associated with higher aqueous solubility, it also tends to be less stable. In fact, one of the problems associated with in vivo drug precipitation (solubilized drug that recrystalizes in vivo) is that the administered amorphous form (which was soluble) precipitates into a higher energy form, thereby leading to bioavailability (solubility) problems. It is for this reason that much attention is currently being given to the development of drug formulations that support in vivo supersaturation (i.e., the drug remains in solution at concentrations greater than its thermodynamic equilibrium solubility), thus leading to enhanced intestinal drug absorption (Gao and Shi, 2012).

Polymorphism is a term used to describe the phenomenon where a drug can exist in more than one crystalline form (i.e., with different lattice arrangements). The difference in molecular arrangement is illustrated in Figure 5.2. The resulting crystal lattice can profoundly influence crystal properties. Polymorphs of an API differ in their solubility, dissolution rate, density, hardness, and crystal shape (Sun, 2009).

An additional consideration is that crystalline forms can exist as anhydrous configurations or as hydrates or solvates. Solvates are crystalline solid adducts containing either stoichiometric (fixed integral ratio) or nonstoichiometric amounts of a solvent incorporated within the crystal structure. If the incorporated solvent is water, then the crystalline form is known as a hydrate. The state of molecular hydration can affect solubility. In general, the anhydrous form of the drug is more soluble than the hydrate due to the stability of the crystalline arrangement (i.e., there is a higher melting point associated with hydrates). For example theophylline is available as either the hydrate or as the anhydrous form. Similar differences in polymorphic forms are also seen with penicillin and caffeine. For each of these compounds, the various polymorphs are characterized by differences in their respective in vitro dissolution characteristics, with the solubility and dissolution rate of the anhydrous crystal exceeding that of the hydrate.

Furthermore, the packing geometry leads to differences in their respective lattice energies. Packing geometry is the orientation or conformation of the molecules at the lattice sites, which leads to differences in the amount of energy required to break the crystalline lattice structure. Thus, polymorphic forms usually exhibit different physicochemical properties, including melting point, bulk density, powder flowability, compressibility, hardness, crystal shape, and solubility.

Since at least one-third of all organic compounds exhibit polymorphism, polymorphic screens are an important tool in the pharmaceutical scientist's arsenal. Evaluation of crystal structure, polymorphism, and solvate form is an important preformulation activity. The changes in crystal characteristics can influence bioavailability and chemical and physical stability. Techniques used to determine crystal properties include hot stage microscopy, thermal analysis, infrared spectroscopy, near infrared spectroscopy, and X-ray diffraction.

Particle Geometry

When considering particle geometry, parameters of importance include size and shape. In turn, these influence packing properties and density.

Size: Particle size can affect such CQAs as dissolution rate, content uniformity, taste, texture, color, and stability. The extent to which some of these factors are influenced by particle size is determined, at least in part, by the aqueous solubility of the API (where particle size is more important for the dissolution of poorly soluble compounds) and by the product formulation (for content uniformity). Particle size reduction is usually accomplished by shearing, impact, attrition, or compression (dry-milling processes). An excellent review on the importance of particle size specifications was provided by Sun et al. (2010).

A reduction of particle size increases the particle's surface area, decreases the diffusion (or unstirred) boundary layer (the stagnant layer of solvent surrounding the particle), and therefore may enhance drug solubility. A further discussion of this relationship is provided in this chapter's section on solubility. However, while an increase in surface to volume ratio via a decrease in particle size can enhance API solubility, there are situations whereby decreasing the particle size can have the opposite effect. For example, the cohesivity of particles (tendency to stick together) increases as the particle size decreases. This is a major issue with nanoparticle formulations. Furthermore, particle size governs sedimentation, the formation of aggregates (also known as flocculation, where smaller particles settle faster than do the larger particles) and crystal growth. Crystal growth occurs when smaller particles dissolve and subsequently recrystallize, whereupon they adhere to larger particles, thereby forming larger crystals (a phenomenon referred to as Ostwald ripening). The seeding effect of larger particles on crystal growth is termed nucleation, and a formulation strategy to suppress nucleation is the use of colloid systems (Ravin and Rodebough, 1980).

With regard to manufacturing processes, particle size distribution will affect powder flow. Particles ≥250 μm are usually relatively free flowing while very fine particles (below 10 μm) tend to be extremely cohesive and flow poorly. The converse is true with regard to blend uniformity where smaller particles typically facilitate content uniformity.

Particle shape: Particles can be characterized by their geometric shape, surface characteristics, and whether they are single particles or are associated as multiparticulate bodies. Shape can influence mixing and tableting processes. The simplest way to describe the shape of a particle is to use a metaphor or to compare it to a commonly known object as in such terms as "egg-shaped" and "granular." The following are some of the commonly used descriptors of particle shape:

- *acicular* - slender, needle-like particles of similar width and thickness.
- *flake* - thin, flat particles of similar length and width;
- *plate* - flat particles of similar length and width but with greater thickness than flakes;
- *lath* - long, thin, and blade-like particles;
- *equate* - particles of similar length, width, and thickness;
- *spherical* - globular shaped.

Dissociation Constants/pKa

The pKa of a drug influences lipophilicity, solubility, protein binding, and membrane permeability. Consequently, it affects such PK characteristics as absorption, distribution, metabolism, and excretion (ADME). Typically, the unionized molecule exhibits greater lipid solubility than does its ionized form. Accordingly, the unionized molecule tends to be the form that can most readily cross biological membranes. Conversely, the ionized form is typically responsible for product dissolution in biological fluids (Kerns and Di, 2004; Avdeef, 2001).

Based upon our knowledge of the drug pKa and the surrounding pH, the relative amount of ionized and unionized drug in solution at a particular pH can be determined. The relationship between pKa, pH, and the relative amounts of ionized versus unionized drug can be estimated by applying the Henderson–Hasselbalch (HH) equation introduced in Chapter 2 (Equations 2.2 and 2.3; Figure 2.3). The underpinnings of the HH equation are described by understanding the behavior of weak acids and bases (Figure 5.3).

Strong acids and bases are those that completely dissociate into ions once placed in solution. Weak acids and bases, however, do not fully dissociate in the solution. Weak acids have a higher pH than strong acids because weak acids do not release all of their hydrogens. The acid dissociation constant tells us the extent to which an acid dissociates.

The ionization of a weak acid is represented by (Equation 5.1):

$$HA + H_2O \rightleftarrows H_3O + A- \tag{5.1}$$

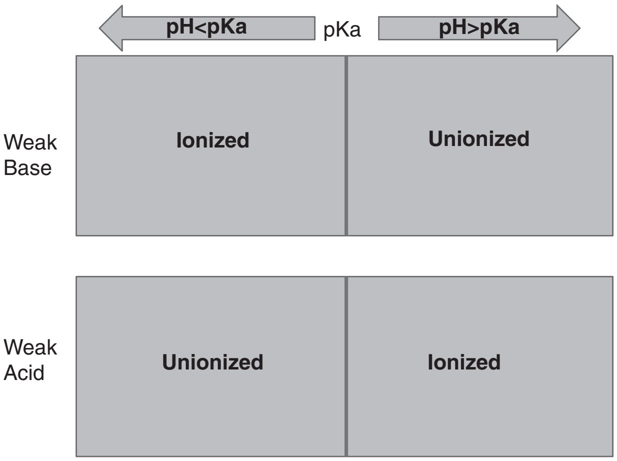

Figure 5.3 The relationship between the preponderance of the ionized versus unionized form of a compound as a function of pKa versus pH for weak acids and weak bases.

The dissociation constant, Ka can be calculated as follows (Equation 5.2):

$$Ka = \frac{(H_3O+)(A-)}{HA} \tag{5.2}$$

The HH equation for a weak acid is described as follows (Equation 3):

$$pH = pKa + log\frac{A-}{HA} \tag{5.3}$$

where A− is the ionized form of the weak acid and HA the unionized form of the drug. Accordingly, when the pH exceeds the pKa, the ionized form of the drug will predominate.

Conversely, for a weak base, pH is defined as follows (Equation 5.4):

$$pH = pKa + \log\frac{B}{BH^+} \tag{5.4}$$

where B is the unionized form of the weak base and BH^+ is the ionized form of the drug. Accordingly, when the pH exceeds the pKa, the unionized form of the drug will predominate.

Based on Equations 5.3 and 5.4, we can calculate the percentage of drug existing in the unionized form at a given pH (Equation 5.5):

$$\%ionized = \frac{100}{1 + 10^{charge(pH-pKa)}} \tag{5.5}$$

where charge = −1 for acids and 1 for bases.

Partition Coefficients

Log P: In most situations, drugs must cross biological membranes before entering the bloodstream. Since biological membranes are lipophilic in nature, there is the competing challenge of solubilization in an aqueous environment versus the need to partition across the lipophilic biological barrier. This fine balance necessitates that the drug can readily pass between the aqueous and lipid phases to insure drug absorption. Figure 2.2 illustrates this concept. This capability is described by the partition coefficient, P, which characterizes the relative oil versus water affinity of a compound when it exists in its unionized form.

The determination of P (or Log P) involves the addition of the API to a separatory funnel that contains a mixture of two immiscible solvents. Drug molecules then distribute between these two layers until equilibrium is established. The resulting estimate, the Log P value, is often used to predict API absorptive capability.

If the compound is acidic or basic, the pH is adjusted to insure the compound is neutralized. Once equilibrium has been achieved, the compound is quantified in each solvent, typically via ultraviolet/visible spectroscopy or by titration, and the logarithm of the concentration ratio is calculated. The measurement is expressed with the following Equation 5.6:

$$\text{Log P} = \text{Log}[(\text{Analyte concentration in Octanol})/(\text{Analyte concentration in water})] \tag{5.6}$$

The resulting Log P value specifies whether the measured compound is hydrophobic or hydrophilic. The reason why octanol is selected as the lipophilic solvent is because it acts both as a hydrogen bond acceptor and donor, thereby simulating the properties of biological membranes (Fletcher et al., 2013).

The interpretation of Log P values relative to permeability predictions are as follow (Lipinski et al., 2001):

- Log P <0 implies that the drug has poor oral absorption. Therefore, parenteral administration may be the preferred method of drug administration.
- Log P = 0–3 implies that the drug has intermediate oral absorption and it can be manufactured as an oral dosage form.
- Log P = 2–4 implies that the drug has high absorption and it can be manufactured as transdermal.
- Log P >4 implies the potential for extensive drug partitioning into fatty tissues, which can lead to drug accumulation.
- Log P>5 implies that the drug exhibits very high lipophilicity and may be unable to traverse across the layers of a biological membrane.

Log D: Another common measure for lipophilicity is the distribution coefficient, Log D. Log D accounts for the existence of molecules both in its ionized and unionized forms. Accordingly, measurements of Log D are generated across a range of pH values. For unionizable compounds, Log P = Log D at any pH. Amongst the different pH values, typically the most interesting is pH 7.4, the physiological pH value.

Melting Point

Each pure substance is characterized by a specific melting point or melting range. The presence of impurities results in a change in the melting point. This phenomenon is commonly used to determine the purity of a drug substance. In addition to its importance regarding the determination of impurities, melting point of the pure API needs to be considered during the manufacturing process. In particular, it can influence the appropriateness of using hot melt extrusion techniques (e.g., chewable dosage forms) or the stability of the product when encountering the heat produced during process granulation.

Rheology

Rheology is a study of the flow and deformation characteristics of a material (liquid or semisolid) when subjected to an applied force. Deformation is the transient change in shape of matter. If the shape of the material reverts to its original state after the stress is removed, the material is said to be elastic (e.g., a rubber ball). Conversely, if the matter does not deform, it is considered to be rigid.

Material flow is dependent on the ability of the material to deform. For example, if toothpaste is placed into a square container and that container is subsequently squeezed, displacing toothpaste into a round container, the toothpaste would take on the shape of the new container. This movement of the toothpaste is defined as flow. Rheologic measurements are used to characterize the ease of flow and the ability of the material to deform. These are important characteristics in the manufacturing process as it influences the ability of the product to maintain its shape after extrusion or the problems that will be encountered during product mixing and storage. The rheological properties of an API can also influence the homogeneity of a formulation.

The ability to deform determines the magnitude of internal friction generated in response to an external stress. In this regard, the greater the deformation properties of the drug, the smaller the friction and the higher the flow rate in response to any given external stress. The measure of resistance to flow is defined as the viscosity of the fluid.

A fluid is considered to exhibit Newtonian flow if the viscosity does not change in response to the application of sheer. An example of a Newtonian fluid is water. In contrast, some non-Newtonian materials (such as yogurt, latex or acrylic paints) exhibit thixotropy (a reduction in viscosity in response to an increase in relative flow velocity by processes such as stirring) while others (e.g., thickening agents) exhibit an increase in viscosity in response to an increase in sheer stress (Wood, 1986).

Chemical Properties

Stability

Stability of the drug substance should be determined in the early phases of product development. A drug product is considered unstable when the API loses sufficient potency that it will adversely affect the safety (e.g., potential for toxic degradants) or efficacy within a timeframe deemed unacceptable for the desired shelf life. Stability testing provides information on the API behavior under a variety of environmental factors such as temperature, humidity, and light. It also establishes a retest period for the drug substance, shelf life for the drug product, and leads to recommendations with respect to drug and drug product storage conditions. Oftentimes, degradation products can be predicted a priori from the chemical structure of the API. For example, esters and amides are sensitive to hydrolytic degradation while acridans and catecholamines are sensitive to oxidative degradation.

Degradation mechanisms include:

Hydrolysis: Hydrolysis is a chemical process that includes degradation of a drug substance by its reaction with water. It typically occurs with esters, amides, and salt of weak acids or strong bases(Alsante et al., 2009).

Oxidation: This process includes the degradation of a drug substance via an electron transfer mechanism, thereby forming reactive anions and cations. Amines, sulfides, and phenols are susceptible to electron transfer oxidation, resulting in *N*-oxides, hydroxylamine, sulfones, and sulfoxide (Gupta et al., 2011). Oxidation can affect the chirality or racemization of some drug substances, leading to altered therapeutic effects (Alsante et al., 2007).

Photolysis: This process includes degradation of a drug substance upon exposure to ultraviolet or fluorescent light. The presence of functional groups such as weak C–H and O–H bonds, nitroaromatic alkenes, aryl chlorides, carbonyls, *N*-oxide, sulfides, and polyenes are responsible for drug photosensitivity. The standard conditions for photostability testing are described in ICH Q1B Photostability Testing of New Drug Substances and Products (ICH, 1996).

Thermal degradation: For some compounds, the addition of heat (thermal energy) can accelerate oxidation, reduction, and hydrolysis reactions.

Humidity: Humidity is a critical determinant of the potential degradants in the finished product (Charde et al., 2013). Chemical stability issues associated with high humidity are generally a result of the hydrolysis of susceptible side chains. High humidity can also facilitate microbial growth. When considering the impact of humidity, it is important to distinguish between free versus bound water. For example, an excipient can contain >10% water but if it is all bound as a crystal hydrate, this moisture will not react with the API. Conversely, if the excipient contains 1% or less of free water, there is a risk that the water associated with that excipient will interact with and alter the API, adversely affecting drug and drug product stability. Drugs containing functional groups such as esters, amides, or lactones are subjected to hydrolysis by water. In these situations, measuring the intrinsic moisture of the formulation is advisable.

Stereochemistry

Stereochemistry is a study of the structural arrangement of the atoms within the molecule or the functional groups in the molecule. Stereoisomers are characterized as having the same composition but differences with respect to its spatial orientation. There are two kinds of stereoisomers: enantiomers and diastereomers. Enantiomers are non-superimposable mirror images. In contrast, diastereomerism occurs when two or more stereoisomers of a compound have different configurations at their stereocenters and are not mirror images of each other. Diastereomers generally have different physicochemical characteristics and therefore are considered to be different compounds.

Whether to formulate a product using a racemate or an enantiomer of a chiral drug (i.e., a drug containing a tetrahedron that results in the presence of molecular forms that are nonsuperimposable mirror images) depends on such considerations as the relative pharmacodynamic activity and the potential toxicity (or side effects) of the individual enantiomers, their pharmacokinetic profiles, and, importantly, the proportions of the individual enantiomers that may form over time in the target animal species (i.e., in vivo chiral inversion) (Baggot, 2007). Furthermore, there can be occasions when one enantiomer of an API is active but the other is not. Use of the racemic mixture leads to half of the administered API being without clinical effect. An example of this is omeprazole versus esomeprazole (Andersson, 2004).

The stereochemistry of the API can also lead to differences in the product dissolution rates. For example, cellulose derivatives, ascorbic acid, mannitol, sorbitol, lactic acid, and malic acid, are examples of chiral excipients that can interact with drug enantiomers and produce stereospecific release and absorption from the formulation.

Geometrical Configuration

Enantiomers are considered to be the same compound but are designated with regard to its geometric configuration. Generally, this is the designation of R or S, reflecting the orientation of each chiral center. R and S forms of a compound can have different biological activities. For example, biological differences due to enantioselectivity are provided in Table 5.1.

An additional geometrical term used to describe the entire molecule is dextrorotatory (D) or levorotatory (L), depending on its exact substituents. D and L symbols are associated with absolute configuration of a molecule, and this designation is based on the absolute configuration of the dextrotatory and levorotatory forms of glyceraldehyde. The D/L system remains in common use in certain areas of biochemistry, such as amino acid and carbohydrate chemistry. Most naturally occurring carbohydrates are nearly all D while most amino acids are L.

Table 5.1 Biological differences between S and R forms of various active pharmaceutical ingredients

API	S Form	R Form
Asparagine	(S) Bitter Taste	(R) Sweet Taste
Chloramphenicol	(S,S) Inactive	(R,R) Antimicrobial
Propranolol	(S) 100 × activity of (R)	
Ethambutol	(S,S) Tuberculostatic	(R,R) Cause blindness
Etodolac	(S) Antiinflammatory	(R) Reduced activity
Verapamil	(S) Cardiovascular effect	(R) Cancer therapy

Optical Rotation

An enantiomer can be named by the direction in which it rotates the plane of polarized light. If it rotates the light clockwise (as seen by a viewer towards whom the light is traveling), that enantiomer is labeled (+). Its mirror image is labeled (−). The (+) and (−) isomers have also been termed d- and l-, respectively (for dextrorotatory and levorotatory). Naming with d- and l- is easy to confuse with D- and L- labeling and is therefore strongly discouraged by IUPAC (Klink et al., 2001).

Solubility

Solubility can be defined as the ability of a substance (the solute) to dissolve in a fixed amount of solvent (e.g., water or buffered solution) to form a saturated solution under a specific temperature and pressure. When the solvent is saturated with solute, the concentration of solute is called the saturation concentration. In the literature, the term *saturation concentration* (C_S) is often used interchangeably with the term *solubility*. Intrinsic solubility for an ionizable molecule is defined as the concentration of the unionized molecule in a saturated aqueous solution, existing in a thermodynamic equilibrium at a given temperature (Horter and Dressman, 2001).

In contrast, when an excess amount of solid is inserted into the solvent, under defined temperature and after sufficient stirring time, the amount of dissolved solute may be initially high but then will reduced to its thermodynamically stable value over time. The time it takes for such a reduction in solubilized concentration depends on several factors, and varies from seconds to months. When the obtained saturation concentrations are much greater than the thermodynamically stable values, the term *apparent solubility* is applied. The term apparent solubility refers to the metastable or dynamic solubility of the materials rather than to a thermodynamically stable state (Mosharraf and Nyström, 2003).

The relationships between dose, dissolution characteristics, and drug solubility can be described in Equation 5.7 as follows (Lobenberg and Amidon, 2000).

$$\text{Dissolution number (Dn)} = (3D/r^2) \times (C_S/\rho) \times \langle \text{Tsi} \rangle \tag{5.7}$$

where

D is the diffusivity of the dissolved drug
ρ is the density of the dissolved drug

C_s is the drug solubility
r is the initial radius of the drug particle
<Tsi> is residence time in the small intestine

The corresponding ratio of dose to dissolved drug i.e., the dose number, D_0, is described by:

$$(D_0) = \frac{M/V_0}{C_S} \tag{5.8}$$

where M is the dose of the drug and V_0 is the volume of fluid consumed with the dose.

Within the pharmaceutical sciences, the focus is on aqueous solubility because water is the biologically relevant solvent. However, it should be kept in mind that, as discussed later in this section, the API must cross biological membranes to exert an effect (e.g., enterocyte, endothelial cell, targeted host cell or a pathogen). Therefore, the relative solubility (partitioning capability) between a hydrophilic and hydrophobic solvent (e.g., octanol versus water) is also a critical consideration when developing drug candidates.

Aqueous solubility is controlled by two opposing interactions. Favoring API solubilization is the interaction between a molecule of the API and the solvent. Counteracting aqueous solubilization is the affinity of the solute for itself. It is the greater of these two effects that dictates the maximum amount of drug that will dissolve per unit volume of solvent. Because many of the more recent drugs exhibit very strong self-affinity (low aqueous solubility), much work is currently being conducted on mechanisms to reduce the strength of these internal interactions, thereby enhancing solubility in aqueous media (Delany, 2005). Pharmaceutical techniques explored for achieving this enhanced aqueous solubility include formulation adjustments or molecular modifications (e.g., new salt forms).

Assessment of drug solubility is not necessarily straightforward as there are numerous variables that affect solubility results. We have already discussed some of these factors, including drug pKa, polymorphisms, particle size and shape, chemical purity, and the potential for molecular stability problems when present in its dissolved state. Several software programs are capable of synthesizing information on these variables into solubility and permeability predictions. Such information can be invaluable both for the formulation chemist and for the pharmacologist who seeks to understand how target animal species-specific in vivo conditions can alter drug product dissolution and drug membrane permeability.

For any set of API chemical characteristics, the solubility of the API in aqueous solutions can be influenced by:

- pH of the solvent: This has its greatest effect on a weakly acidic or weakly basic API. Because it is the ionized form of a molecule that exhibits the greatest aqueous solubility, weak acids typically have its highest aqueous solubility at pH values above their pKa. Conversely, weak bases tend to dissolve better at pH values less than that of their pKa. For that reason, pharmaceutical scientists frequently examine drug solubility across a pH range of 1 to 7.5 (i.e., a range typically encountered in monogastric species).
- Buffer composition: Solubility may be different in different buffers even if the medium is maintained at the same pH. This buffer effect is due to the possible formation of a poorly dissociated compound between the API and the counter-ion in the buffer.
- Common ion effect: The presence of a common ion in the solvent (e.g., contributed by the buffer) and the API can decrease the ionization of the API by a mass effect (i.e., accumulation of the counter-ion towards its own solubility limits will cause the counter-ion to exert a concentration gradient favoring the drug molecule to remain in a solid form).
- Ionic strength: The ionic strength of a solution is a measure of the concentration of ions in that solution. The total electrolyte concentration in solution will affect the dissociation or the solubility of different salts. Since the strength of the common ion effect depends on its concentration (by mass effect), the higher the ionic strength the lower will be the solubility of the API. Apart from the presence of a common ion, the API may have an optimal solubility at a certain ionic strength and minimal solubility at another ionic strength.
- Type of additive: Polar compounds like acids, bases, salts, alcohol, and sugar are very soluble in polar solvents like water. However, nonpolar compounds are uncharged (such as many steroids) and often require the presence of additives, including cosolvents and surfactants:
    - Cosolvent: This is the second solvent which is added in small quantities to enhance the solvent power of the primary solvent. Examples include, dimethylsulfoxide (DMSO), propylene glycol, and various alcohols (such as polyethylene glycol).
    - Surfactant: Surfactants are typically organic compounds that contain both a hydrophobic head and a hydrophilic tail. As a result of their structure, they lower the surface tension (or interfacial tension) between two liquids or between a liquid and a solid. In so doing, the surfactant can act as detergents, wetting agents, emulsifiers, foaming agents, or dispersants. Examples of surfactants include polysorbates, polyoxyethylated castor oil, polyoxyethylated glycerides, lauroyl macroglycerides, and mono- and difatty acid esters of low molecular weight polyethylene glycols (e.g., lipids, surfactants) which are miscible in aqueous fluids, serving to enhance the drug–water interaction.

- Temperature: The effect of temperature will depend upon whether the solubilization process is endothermic (heat absorbing) or exothermic (heat producing). The dissolution of a solid solute and aqueous solvent is generally endothermic. Therefore, an increase in temperature will increase drug solubility. Conversely, when the solute is a gas, its dissolution in water tends to be an exothermic reaction. Accordingly, any increase in temperature will reduce gas–liquid solubility.
- A review of pharmaceutical efforts to enhance drug solubility was provided by Savjani et al., 2012.

Permeability

As discussed by Martinez and Amidon (2002) as well as in Chapter 2 of this text, molecular movement across lipid bilayers, such as those within biological membranes, is extremely complex due to the regional differences in membrane polarity, hydrophobicity, and density. Generally, the bilayer can be divided into four distinct regions. These are:

- the first (outermost) region, which contains a high proportion of water molecules;
- the second region, which has the highest molecular density of all four regions (contains the polar headgroups), contains little or no water, and exerts the greatest barrier to solute diffusion (due to its density characteristics);
- the third region, which contains the highest density of nonpolar tails and is primarily responsible for the limitations in molecular size and shape associated with membrane transport;
- the fourth region is the most hydrophobic region of the membrane, serving as a hydrophobic barrier in membrane transport.

Owing to the anatomy of this complex barrier, drug permeability is not a simply two-step process of solubilization and diffusion. Rather, it represents a spectrum of complex molecular events. Accordingly, membrane penetration reflects the interaction of several factors, including molecular size (negatively correlated), lipophilicity (positively correlated), polar van der Walls surface area (negatively correlated), and the molecular flexibility (intramolecular hydrogen bond formation).

Molecular flexibility and the corresponding ability to undergo conformation changes can significantly affect the polar surface area of a molecule. The polar surface area and nonpolar surface area are predictors of intestinal permeability, being respectively inversely and directly related to membrane permeability. Another important variable is the strength of the hydrogen bonds formed between the molecules of water and solute. It is generally assumed that these bonds must be broken (desolvation) before the solute can traverse the biological membrane.

Impurity can affect stability, appearance, and API toxicity, (e.g., aromatic amines, suspected of being carcinogenic). In most cases, the impurities (reactive species) consist of water, small electrophiles (such as aldehydes, carboxylic acid derivatives, and peroxides), and metals. Water can hydrolyze some drugs. Aldehydes and carboxylic acids can form molecular adducts. Peroxides can oxidize some drug. Metals can catalyze oxidation, hydrolysis, and other degradation pathways (Fahmy et al., 2008). Impurities can lead to altered bioavailability, toxicity, or a reduction in effectiveness.

Formulation Elements

There are more than 800 excipients currently used in marketed pharmaceutical products within the United States (human and veterinary). This number is expected to increase to accommodate the evolution in therapeutic entities such as those associated with gene and cell therapy or the development of new drug delivery platforms (Bhattaryya et al., 2006).

The purpose of excipients varies as a function of the drug, dosage form, and the intended in vivo release characteristics. Pharmaceutical excipients may be used for any one (or combination) of the following objectives:

- aid in the processing of the dosage form during its manufacturing and provide the desired drug delivery characteristics;
- enhance solubility and bioavailability of the active ingredient;
- enhance palatability to some dosage forms (tablets, chewable, suspension, solution, etc.);
- maintain pH and osmolarity of liquid formulation;
- control the drug action inside the body;
- enhance the overall stability of the drug during the shelf life;
- provide physical, chemical, and microbiological stability to the dosage form.

Both synthetic and natural ingredients have been used as excipients in pharmaceutical products. Examples include:

- Natural products: Gelatin, acacia, agar, shellac, starch, gums, beeswax, oils, lanolin, vanilla, coco butter, sugars, and cellulose. Note that some cellulose-based excipients are less frequently used in recent formulations due to their tendency to exhibit lot-to-lot variability and due to their potential to act as substrates encouraging fungal and bacterial growth.
- Semisynthetic products: These provide less variability than natural products, helping the formulator design a consistent product, and include synthetic derivatives

of cellulose (e.g., microcrystalline cellulose, hydroxyethyl cellulose, hydroxyethylmethyl cellulose, cellulose acetate phthalate, hydroxypropyl cellulose).
- Synthetic products: These usually originate from petroleum products or byproducts, typically exhibit consistent physicochemical properties, and do not support any microbial growth. Examples are povidione (PVP), polymethacrylates, polyethylene glycol, polyethylene oxide, and polyvinyl alcohol.

For excipients not described in any pharmacopoeia, specifications should include physical characterization, identification tests, purity test, assay, and impurity tests. As with human pharmaceuticals, all excipients used in the veterinary medications are manufactured and supplied in compliance with compendial standards and should comply with the United States Pharmacopeia (USP) or National Formulary (NF) monographs or with any other recognized pharmacopeia.

The Food and Drug Administration (FDA) approves all excipients that are included in pharmaceutical products. A certification of analysis (COA) must confirm that excipients are of nonanimal origin. If this is not the case, the regulatory agency requires documentation to demonstrate freedom from viral and transmissible spongiform encephalopathies (TSE) and bovine serum encephalopathy (BSE) risks.

Excipients from an animal origin should be identified. The genus, species, country of origin, source (e.g., pancreas), and manufacturer or supplier should be clearly indicated. Furthermore, for excipients derived from ruminant materials, the application should state whether the materials are from BSE countries as defined by the US Department of Agriculture (9 CFR 94.11). Guidance is available from the FDA on *The Sourcing and Processing of Gelatin to Reduce the Potential Risk Posed by Bovine Spongiform Encephalopathy (BSE) in FDA-Regulated Products for Human Use*. The potential adventitious agents should be identified, and general information regarding control of these adventitious agents (e.g., specifications, description of the testing performed, and viral safety data) should be provided in this section. Details of the control strategy and the rationale for the controls should be provided.

Additional guidance is available in International Conference on Harmonization (ICH) guidelines:

ICH: *Q5A Viral Safety Evaluation of Biotechnology Products Derived From Cell Lines of Human or Animal Origin*
ICH: *Q6B Specifications: Test Procedures and Acceptance Criteria for Biotechnological/Biological Products.*

It is critical that the API and excipients do not interact with each other and/or the container over time. If interaction occurs, product quality and performance can be compromised. An additional consideration is the safety of the excipient. The safety of a particular component of human food and drugs does not necessarily insure its safety for consumption by a veterinary species. For example, xylitol, a popular human sugar substitute was found to be highly toxic, or even fatal, when given to dogs.

Some excipients have their own inherent activity that can influence drug pharmacokinetics. For example, the vitamin E derivative, α-tocopherol polyethylene glycol 1000 succinate (TPGS), when administered at low concentrations, appear to enhance the secretion of chylomicrons by enterocytes. In turn, this can lead to a significant enhancement of intestinal lymphatic transport of lipophilic drugs. In addition, several reviews show that a number of excipients can influence the in vivo and in vitro activities of a variety of cytochrome P450s (CYPs) or membrane transporter activities (Ren et al., 2008; Buggins et al., 2007).

For any given dosage form, the excipient is selected to achieve a specific function. While there can be multiple choices of excipients, the final selection is based upon its specific properties and how it will impact product in vivo performance, stability, and ease (and uniformity) within the manufacturing process. In the next section, we provide a brief overview of the functional considerations that go into the determination of excipients included in solid dosage forms.

Excipients Typically Used in Veterinary Dosage Forms

The following are some examples of the common excipients and their functionalities used in manufacturing different veterinary dosage forms.

Excipients for Solid Dosage Forms

Examples of commonly used dosage form-specific excipients are described below.

Fillers (Diluents): Diluents are added to a formulation to increase the bulk volume of the API, making the size of the tablet suitable for handling. They also can improve the product manufacturing properties (e.g., powder flow, compaction properties, and homogeneity) and product quality, such as content uniformity, in vivo disintegration and dissolution, tablet integrity, friability (the ease with which tablets can break into smaller pieces, promoting more rapid dissolution), or physical and chemical stability. The selection of diluents depends on the type of processing and the plasticity (the capability to be deformed) of the materials to be used. Examples of diluents used in veterinary medicine include: microcrystalline cellulose (MCC), lactose, dicalcium phosphate (Di-Cal), mannitol, sucrose, and partial pregelatinized starch.

Binders: Binders are used for the purpose of holding together the ingredients in a formulation, thereby ensuring that granules and tablets can be formed with the required mechanical strength. It also affects the disintegration rate, dissolution rate, hardness, and friability (Jayesh and Manish, 2009). Examples of excipients that are added to a formulation in a solid form include hydroxypropyl methylcellulose, polyvinylpyrrolidone (PVP), starch, and polyethylene glycol. Alternatively, it could be dissolved in solvents and added to the powder to form wet granulation such as gelatin, PVP, starch, sucrose, and polyethylene glycol (PEG).

Disintegrants: Disintegrants are added to promote moisture penetration into the dosage form matrix, thereby ensuring that it will break into small fragments. The formation of smaller tablet particles allows for an API to undergo a more rapid dissolution. Disintegrants can be added to tablets and hard shell capsule formulations (i.e., the drug plus formulation administered as a solid substance enclosed in a capsule). The quality and quantity of the disintegrant affects the product's dissolution and therefore the bioavailability of the API. Examples of common disintegrants used in veterinary medicine are: starch, (MCC), croscarmellose sodium, and crosspovidone.

Glidants: Glidants are used to promote powder flow within the manufacturing machinery by reducing interparticle friction and cohesion. Glidant particles coat the surfaces of the larger bulk powder particles ('host particles') where they may reduce of surface roughness and attractive forces, or act as moisture scavengers. Examples of glidants are: talc powder, sodium lauryl sulfate, colloidal silicon dioxide, and starch.

Lubricants: Lubricants are added to formulations to prevent its sticking to the manufacturing equipment. Although there are both hydrophilic and hydrophobic lubricants, it is the latter that is more effective in achieving the desired manufacturing benefit and therefore is the one generally used in tablet formulations. Commonly used hydrophobic lubricants include magnesium stearate, calcium stearate, and stearic acid. Of particular note for these hydrophobic (waxy) lubricants is that the dissolution rate of poorly soluble APIs is influenced not only by the amount of lubricant added to the formulation but also by the order of its addition relative to the other constituents and the blending time of the lubricant with the other ingredients. This effect appears to be attributable to the smearing of the hydrophobic lubricant (e.g., magnesium stearate) over particle surfaces, resulting in a reduction in product in vivo absorption (Kalyana et al., 2011).

Coating agents: Tablet coating is used to improve product appearance, to provide taste/odor masking, to facilitate swallowing, to protect from moisture/light, to improve mechanical strength, and as a mechanism for modifying drug release (e.g., enteric coated tablets). Examples of coating agents include sugar, hydroxypropyl methylcellulose (HPMC), cellulose acetate phthalate (Aquacoat® CPD; enteric), ethylcellulose (sustained release), hydroxypropyl methylcellulose acetate succinate (enteric), and polyvinyl acetate phthalate (enteric).

Excipients for Modified Release Formulations

Excipients used in modified release (MR) tablets fall into two broad groups based on whether they are cellulose or acrylic polymers. The most common technique for producing a MR tablet is either through the formation of matrices or by the inclusion of special tablet coatings.

Matrix tablets: The most common excipients for the matrix tablets are sodium carboxymethylcellulose, HPMC high viscosity, a carboxyvinyl hydrophilic polymer, and PVP.

Coated tablets The most common excipients for coated tablets are ethyl cellulose (the most frequently used cellulose-based polymer used for extended release) and PVP.

Excipients Typically Used in Liquid and Semisolid Formulations

Bulking agents: These excipients are generally used to increase the mass of a lyophilized product, thereby providing structure to the formulation. Bulking agents are used for low-dose, high-potency drugs (when the API constitutes less than 2% in the formulation) and therefore does not have the bulk necessary to support its own structure. Examples of bulking agents include mannitol, lactose, and sucrose.

Buffering agents: The choice of buffer depends on the pH stability profile of the API. Buffer selection, along with its concentration is important to avoid API degradation during processing or during storage and reconstitution. Buffer selection also influences the optimization of product solubility. Commonly used buffers in the parenteral formulations are acetate, citrate, tartrate, phosphate, triethanolamine (TRIS), benzoate sodium /acid, boric acid/sodium, arginine, hydrochloric acid, sodium hydroxide, succinate sodium, sulfuric acid, and sodium carbonate.

Tonicity adjusting agents: Injectable formulations should preferably be isotonic to prevent osmotic shock at the injection. Examples of commonly used tonicity adjusting agents are alkali metal or earth metal halides such as $CaCl_2$, KBr, KCl, LiCl, NaI, NaBr, NaCl, Na_2SO_4, or boric acid. Nonionic tonicity agents include glycerol, sorbitol, mannitol, propylene glycol, or dextrose.

Preservatives: The typical preservatives used in liquid formulations include a range of antioxidants, antimicrobial agents and chelating agents (Chaubal et al., 2006).

Antimicrobial agents: These are used to stop the growth of any microorganisms in the drug product. Examples include benzyl alcohol, parabens (methyl, propyl, butyl), benzoic acid, phenol, thimerosal, meta-cresol, benzalkonium chloride, chlorobutanol, glutathione, and others.

Chelating agents: Chelating agents (substance that bind with free metals such as Cu^{+}, Cu^{2+}, Fe^{2+}, and Fe^{3+}), are generally permitted to be present in trace amounts in the formulation. Since the newly formed complex ions are nonreactive, chelating agents remove the capacity of the metal catalysts to participate in oxidative reactions. Chelating agents also have the ability to enhance antimicrobial effectiveness by forming a metal-ion–deficient environment that otherwise could feed microbial growth. Examples of chelating agents include sodium calcium, ethylenediaminetetra acetic acid EDTA, diethylenetriaminepenta acetic acid (DTPA), calteridol, and disodium EDTA.

Antioxidants: These are used to prevent or minimize oxidation reactions over the shelf life of the product. The most commonly used antioxidants in sterile formulations are ascorbic acid, acetylcysteine, sulfurous acid salts (bisulfite, metabisulfite), and monothioglyercol.

Solubilizing agents: Water is a common solvent system. However, nonaqueous water-miscible agents are used as cosolvents with water to enhance the solubility, stability, and to control drug release from injectable products. Those solubilizing agents, added to the injectable products to enhance the drug solubility into the formulation, are generally classified as surfactants or cosolvents. In contrast to surfactants, which increase API dissolution by reducing the surface tension of the chemical substances, cosolvents are defined as a second solvent that is added in small quantities in conjunction with the primary solvent to increase the API solubility. For compounds with large hydrophobic groups and high Log P values (e.g., 3–4), the use of cosolvents in combination with surfactants may be required (Pramanick et al., 2013). Examples of surfactants are polyoxyethylene sorbitan monooleate (Tween 80), sorbitan monooleate polyoxyethylene sorbitan monolaurate (Tween 20), lecithin, and polyoxyethylene–polyoxypropylene copolymers (Pluronics). Examples of cosolvents include propylene glycol, glycerin, ethanol, polyethylene glycol (300 and 400), sorbitol, dimethylacetamide, and cremophor EL.

Complexing and dispersing agents: Complexation is sometimes used to improve the solubility of drug in the solvent, especially water. Cyclodextrins have emerged as very effective additives for solubilizing hydrophobic drugs. In the parenteral dosage forms, modified cyclodextrins such as hydroxypropyl-β-cyclodextrin and sulfobutylether-β–cyclodextrin have been reported to be highly efficient solubilizer/stabilizers (Loftsson et al., 1996).

Flocculating/suspending agents: Flocculating agents are used in parenteral suspension injectable products to enhance particle “dispersability,” reduce sedimentation rate in the flocculated suspension, prevent cake formation, and control viscosity. Examples of flocculating agents are potassium/sodium salts such as the chloride, citrate, and acetate (all used primarily in parenteral formulations). Other suspending agents (which may be used in nonparenteral or parenteral formulations) include sodium carboxymethyl cellulose, acacia, gelatin (generally for oral formulations), methyl cellulose, and PVP (Anderson et al., 2006). It should be noted that carboxymethyl cellulose may cause allergic reaction in humans, horses, and cattle (Deweck and Schniede, 1972).

Wetting agents: These excipients are used to create a homogenous dispersion of solid particles in liquid media. The majority of drugs in aqueous suspensions are hydrophobic and are therefore difficult to suspend. Consequently, they tend to float on the surface of any polar liquid due to entrapped air and poor wetting. The inability of particle wetting reflects a high interfacial tension between material and liquid. Consequently, the interfacial tension must be reduced so that air can be displaced by liquid. Wetting agents are surfactants that lower the interfacial tension and contact angle for solid particles and liquid vehicle. Examples of wetting agents include anionic substances (such as sodium lauryl sulfate, sulfonate sodium, and docusate sodium), cationic substances (such as cetylpyridinium chloride), zwitterions (such as lecithin), and nonionic substances (such as poloxamer and polysorbate). It is the nonionic surfactants that are most commonly used as wetting agents in pharmaceutical suspensions.

Thickening agents: Commonly used naturally occurring thickening agents are acacia, agar, cellulose, and gelatin. Synthetic thickening agents include methylcellulose, microcrystalline cellulose, and colloidal silicon dioxide.

Coloring agents: Coloring agents can be classified as soluble in water (dyes) or insoluble in water (pigments). The colors approved for the clear liquid formulations are limited to dyes. Examples include sunset yellow, methyl blue, quinine yellow, and FD&C red.

Humectants: These substances prevent drying or loss of moisture from a product commonly used in semisolid preparations. Examples include glycerin, propylene glycol, and sorbitol.

Flavors These substances are used to conceal or mask the bitter, salty, or offensive taste or odor of a drug substance.

Dosage Form Considerations

Pharmaceutical dosage forms contain both pharmacologically active compounds and excipients. For any given product, its quality and performance will be a function of the physicochemical properties of the API, the excipients, and the manufacturing process.

APIs are formed into dosage-form products before they are dispensed or administered to animals. The API is mixed with excipients, such as binders, fillers, flavoring and bulking agents, preservatives, and antioxidants. These ingredients may be dried, milled, blended, compressed, and granulated to achieve the desired properties before they are manufactured as a final formulation.

Examples of the dosage form classifications commonly found within the framework of veterinary medicine are provided below (Figure 5.4). Each dosage form is tailored to meet the needs of the specific animal species, the disease condition (e.g., intramammary) or therapeutic goal (intervaginal implants for estrus control), conditions of use (e.g., in hospital, at home use, mass herd treatment).

Types of Dosage Forms: Liquids and Semisolids

Solutions: Solutions are a clear, homogeneous liquid dosage form that contains one or more APIs dissolved within a vehicle. Solutions are a stable system (i.e., the molecules or the ions do not settle out). Particles are not visible, even under highest magnification, but the solute itself could differentially absorb visible light, leading to color. Depending upon its intended route of administration, the solution may or may not need to be manufactured as a sterile product. In cases when the API is poorly soluble, the formation as a solution may necessitate the addition of solvents such as alcohol, propylene glycol, or glycerin.

Formulations for oral solutions include solvents, buffers, preservatives, antioxidants, and flavors. Challenges with the manufacture of a solution include API solubility, formulation stability (due to oxidation, pH, temperature, and light), sterility (for some routes), and the potential for microbial contamination. Quality attributes include appearance, pH, assay, impurities, and microbial limit.

Suspensions: A liquid suspension is a dosage form containing solid particles dispersed in a liquid vehicle. Unlike solutions, suspensions are considered to be thermodynamically unstable (i.e., capable of separation). Suspensions are for the administration of insoluble or poor soluble drugs.

The suspension system consists of two phases: the internal phase, which contains the solid particles that are characterized by a specific size distribution; and the external phase (suspending medium), which while often

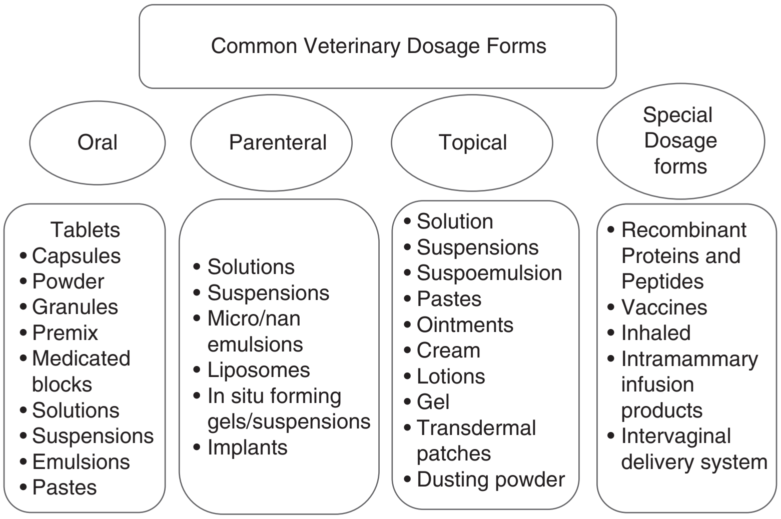

Figure 5.4 Examples of common veterinary dosage forms as a function of route of administration.

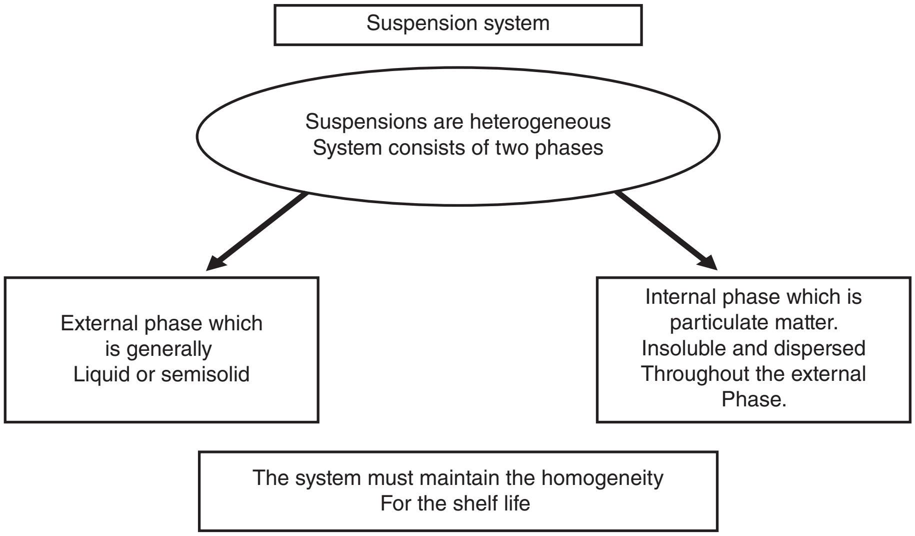

Suspension system
Suspensions are heterogeneous System consists of two phases
External phase which is generally Liquid or semisolid
Internal phase which is particulate matter. Insoluble and dispersed Throughout the external Phase.
The system must maintain the homogeneity For the shelf life

Figure 5.5 Considerations that need to be applied when formulating a drug product as a suspension.

aqueous, can also be organic or oily. This is illustrated in Figure 5.5.

Suspensions can be classified according to their particle size:

- Course suspensions contain particles exceeding 1 μm in diameter.
- Colloidal suspension contain particles less than 1 μm in diameter.
- Nanosuspensions contain particles diameters equal to or less than 100 nm.

There are several challenges encountered during the development of suspensions. These include:

- the electrostatic forces that can lead to particle clumping;
- identification of a vehicle that is compatible with the density of the solid particles. If the density of the particles is greater than the vehicle, the particles will settle downwards (sedimentation). Conversely, if the density of particle is less than that of the liquid medium, particles will move upward (creaming);
- particle size control;
- viscosity, which influences handling of the material during manufacturing and by the end user;
- rate of settlement and resuspendability;
- stability and shelf life.

Formulations for suspension include surfactants, buffers, suspending agent, thickening agents, preservatives, antioxidants, and flavors. When dealing with formulations containing two phases (e.g., solid and liquid), there exists an electrical interactive force. Particles contain an electrical charge in polar solvents. The resulting interactions, the electrokinetic potential measured as the zeta potential, will dictate both in vivo and in vitro particle behavior. Quality attributes thus include particle size distribution, pH, rate of settlement, viscosity, dissolution, zeta potential, and flocculation (formation of aggregates).

Within the framework of a suspension, there are several related dosage forms that differ from the perspective of its physical properties, impact on bioavailability, ease of use, and suitability for route of administration (e.g., oral, topical, parenteral). These include:

- Emulsion: Emulsions are a fluid system consisting of two immiscible phases, leading to liquid droplets (containing the API) which are dispersed in the solvent. The droplets may be amorphous, liquid–crystalline, or any mixture thereof. The diameters of the droplets constituting the dispersed phase usually range from approximately 10 to 100 μm (i.e., the droplets may exceed the usual size limits for colloidal particles). An emulsion is termed an oil/water (o/w) emulsion if the dispersed phase is an organic material and the continuous (solvent) phase is an aqueous solution. Conversely, a water/oil (w/o) emulsion consists of an aqueous dispersed phase that is dispersed in a hydrophobic (oil) phase (Desu et al., 2014). As is the case with other suspensions, emulsions are thermodynamically unstable, thereby necessitating the inclusion of an emulsifying agent to prevent the coalescence of the dispersed droplets (by a reduction in particle interfacial tension). Emulsions formulations typically include oil, preservative, antioxidants, emulsifying agents, buffers, and flavor. Challenges associated with the manufacture of emulsion dosage forms include flocculation or creaming, aggregation, phase inversion, and microbial contamination. Corresponding CQAs include viscosity, content, impurities, pH, rate of settlement, particle size, zeta potential, and aggregation (Nichols et al., 2002).

- Suspoemulsion: A suspoemulsion (SE) is a combination of a suspension and emulsion. It is a mixture of water-insoluble APIs dispersed in an aqueous solution, where one (or more) of the active ingredients is in suspension form and one (or more) of the active ingredients is in emulsion form. The formulation is intended for dilution into water prior to spray application. The continuous phase is comprised of water in which both solid particles and emulsion droplets distribute. This formulation type is especially suitable whenever there are two active substances with different solubility profiles. Suspoemulsions are easy to handle and measure, dust free, nonflammable, and offer good miscibility with water. However, they may need to be mixed before use because of potential stability problems.

Pastes: A semisolid dosage form containing a large proportion (20–50%) of solids finely dispersed in a fatty vehicle. Vehicles used in the formulation of paste and gels include aqueous solvents (least expensive and poses minimal toxicity), oil, or organic solvents. Challenges associated with the manufacture of pastes and gels include producing the desired viscosity, cohesiveness, lack of plasticity, and the need to avoid a separation of liquid and solid components of the formulation. Typically, glycerin, glycols, natural or synthetic gums, and polymers are used to increase the product viscosity while balancing formulation plasticity and cohesiveness. To overcome the separation of water from the gel, absorbing materials such as MCC, kaolin, colloidal silicon dioxide, and starch can be used. Preservatives may be added to inhibit microbial growth.

Gels: A semisolid system in which a liquid phase is constrained within a three-dimensional cross-linked matrix.

Lotions: Suspensions (emulsified liquid dosage form) intended for external application (e.g. calamine lotion, hydrocortisone lotion).

Cream: A cream is a semisolid emulsion systems (o/w, w/o) containing more than 10% of water. Oil in water creams are more common than water in oil because the former tends to be more comfortable to the user, due at least in part to the property of feeling less greasy.

Ointment: An ointment is a highly viscous or semisolid preparation intended for external application.

Types of Dosage Forms: Solids

Tablets: Tablets are compressed powders prepared by one of three general methods: wet granulation, dry granulation (roller compaction or slugging), and direct compression. Issues associated with manufacturing processes are described elsewhere is this chapter. Tablets can be classified on the basis of route of administration (e.g., oral, sublingual, rectal, vaginal, and subcutaneous implant) or formulation characteristics (e.g., immediate release, MR, effervescent, melt in mouth, chewable, flavored, or fast dissolving). In all cases, the general manufacturing processes, technique used for preparation of tablets, and materials are similar.

Immediate release (IR): IR tablets typically dissolve in gastrointestinal contents with no purposefully generated delay in drug dissolution or absorption.

Modified release (MR): MR tablets are manufactured with the purpose of altering the in vivo drug release/dissolution. MR tablets can be in the form of extended or delayed release.

Extended release (ER): Expressions such as "extended release", "prolonged-action," "repeat-action," and "sustained-release" have been used to describe these dosage forms. However, the term "extended-release" is used for pharmacopeial purposes.

ER tablets are formulated to cause the formulation rather than the API to serve as the rate-controlling factor in drug dissolution/release. In so doing, the API can be released over a prolonged duration of time. For orally administered products other than those intended for gastric retention, the success of the formulation is determined by its ability to be absorbed throughout the GI tract. Thus membrane permeability and GI transit time of the target animal species may limit the utility of these formulations in veterinary medicine.

ER formulations can be designed for first-order or zero-order drug release. First-order release is characterized by a specified percentage of the label dose being released over time. A zero-order release of drug is characterized by a specified amount of drug released over time. Chapter 2 should be consulted for more details on the impact of rate-limiting processes on drug pharmacokinetics. Preference is dictated by the absorption properties of the drug and the API exposure–response relationship. The altered drug release characteristics may be achieved through the use of matrix systems (e.g., hydrogels, polymeric matrix, and wax matrix), multiparticulate systems (e.g., granulates, pellets, and beads), polymeric film coating, ion exchange resins, pH-dependent release methods (e.g., enteric coating), and laser drilling. Some of these methods are best achieved by using a capsule rather than a tablet dosage form.

Delayed release: Generally, delayed release tablets are designed to constrain the release of the drug substance until the tablet has passed through the stomach. Delayed release tablets are desired when the drug may be destroyed or inactivated by the gastric juice or when it may irritate the gastric mucosa. Delayed release can be accomplished through the use of enteric coatings.

Bolus: The bolus is a very large tablet that is intended to be retained in the rumen. A slow dissolution process and ruminal retention provides an opportunity to achieve prolonged systemic drug exposure. The release of the active ingredient generally relies on erosion, diffusion from a reservoir, dissolution of a dispersed matrix, or an osmotic "driver." Regurgitation during rumination is prevented by formulating the bolus with a density of $\sim 3\ \text{g/cm}^3$. Critical quality attributes include assay, content uniformity, dissolution, hardness, friability, impurities, and loss on drying.

Implants: An implant is a small tablet that is manufactured in the same way as a tablet. It is a nonoral dosage form that can remain in the body of the animal for many months. They can be either immediate or MR. It is important to recognize that there are numerous variables that can influence the drug release properties of an implant. For example, drug can diffuse both vertically and horizontally. Therefore, the dimensions of the implant and the diffusivity of the drug within the implant matrix can have significant impact on the in vivo rate and extent of drug release. Furthermore, in some cases, implants are manufactured as multilayer products such that the diffusion of drug through each layer can be controlled. Lastly, there are also implants that work as hydrostatic pumps such that the drug is pushed out as water from the tissues move in (Kleiner et al., 2014). Critical quality attributes include assay, content uniformity, dissolution, impurities, and loss on drying.

Chewable tablets: The development of chewable tablets for dogs and cats started in the 1960s, a time when the companion animal pharmaceutical products were produced with the same or similar design and formulation characteristics as compared to the human pharmaceutical. In the mid-1970, the first "chewable" veterinary tablets were developed for dogs, manufactured using standard pharmaceutical processing equipment. Most of these chewable tablets were manufactured by wet granulation technology using water and corn syrup. The early canine chewable tablet formulations were associated with palatability scores of 70–85%. Feline free choice palatability did not fare as well, often with palatability scores of less than 50%. In the 1980s, milk and cheese flavors were tried in for both dogs and cats. Canine palatability never exceeded 80% free choice acceptance and feline palatability never exceeded 70%. Fruit flavors were common in companion animal chewable oral liquids, but fruits are not part of a companion animal's natural diet. Garlic, which has long been considered palatable to dogs, resulted in a free choice acceptance of only about 30–60%. When the garlic flavor was removed and a different flavor system used, a free choice level of 95% was achieved.

The initial palatability enhancing agents often included animal by-products of questionable quality and reproducibility. Common palatability enhancing agents included bovine pancreas digest, bovine liver extracts, bovine meat by-products, fish meal, fish digest, and other ingredients that were not fit for human consumption. The high fat content of these flavors made them prone to rancidity. Even if stabilized with antioxidants, rancidity was an important stability issue (Fahmy et al., 2008). Furthermore, the animal and fish by-products often had very high microbiological counts (greater than 50,000 cfu/g) and were contaminated with *Escherichia coli*, salmonella, and other coliform bacteria. This bacterial growth caused the chewable tablets to turn from brown to green and to emit offensive odors (Meijboon and Stronk, 1972).

In the early 1990s, the industry started to develop alternative chewable tablet formulations with improved flavoring agents that provided an attractive aroma and taste which led to an increase in free choice acceptance. Today, the new flavoring agents meet human food-grade and/or pharmaceutical grade quality standards, are stable and consistent, and contain negligible to nondetectable levels of bacteria, mold, yeast, and fungi.

Chewable tablets can be made by direct compression, wet granulation (using an appropriate solvent), or dry granulation (slugging or roller compaction), extrusion, or produced in a forming machine. "Direct compression" is easy to apply and necessitates minimal capital investment. As this new palatable chewable tablet is formulated, tablet weight and hardness become important variables. For example, when formulating feline chewable tablets, the generalized "ideal" hardness is in the range of 3–4 Kp. All other factors being held constant, as hardness exceeds 6 Kp, the palatability tends to decrease. The identical formulation at 6 Kp tablet hardness may have a 95% free choice acceptance in cats, but only 50% free choice when formulated with a 12 Kp tablet hardness.

The excipients are selected so that the blend can be formed into shapes through a forming machine. In this process, the dry components, which include the API, flavor, fillers, binder, lubricant, and any other ingredients, may be milled and blended. The solvents are added and are mixed until a dough is formed that has the desired texture. The dough batch is divided into portions in accordance with the sublot designation of the configuration being manufactured. The dough sublot is transferred to the forming machine hopper, producing a range of shapes or chews and dosage form weights that can be as high as 15 g. Once the chews are formed, they are taken

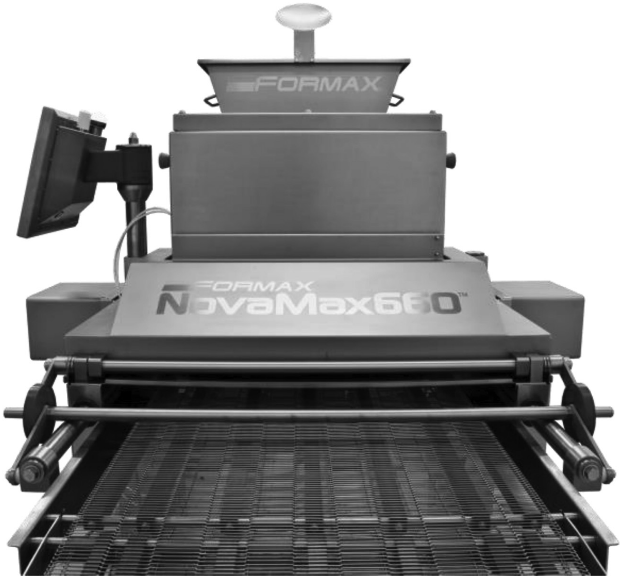

Figure 5.6 Forming machine for chewable dosage forms, *Source:* Courtesy of Provisur.

to either an oven at 40–50°C and/or left at room temperature with relative humidity 40–70% (for up to 7 days depend on the nature of the polymer or the formulation) for curing. An example of a chewable forming machine is provided in Figure 5.6.

Critical quality attributes include appearance, assay, content uniformity, dissolution, impurities, and loss on drying.

Capsules: Capsules are a solid dosage form in which the drug is enclosed in a hard or soft soluble shell. The shells are usually made from a gelatin, cellulose, or polymeric material. The shells may be "hard", consisting of two pieces (a body and a cap) that is typically filled with powder or beads. The hard capsules may be used as a mechanism for achieving extended drug release through such technologies as beads and osmotic pumps (Liu et al., 2014; Becker et al., 2014).

Alternatively, the shell may be "soft", consisting of a single piece (unit) that is typically filled with a solution or suspension containing the API. Soft capsules are often used for formulating poorly water-soluble drugs as a method of enhancing in vivo dissolution. Another advantage offered by the use of single unit capsules is that it avoids potential problems in achieving content uniformity.

The potential for undesirable formulation effects need also be considered when selecting between hard or soft shell capsule formulations. In particular, because the contact between the shell wall and its liquid contents is more intimate than in dry-filled capsules, there is an increased risk of such interactions as gelatin crosslinking and pellicle (thin skin or film) formation. Quality attributes of capsules include assay, content uniformity, impurities, and dissolution.

Powders: The API is mixed with other excipients to produce a final product for oral administration. Drug powders could be added in a solid form or feed, formulated as a soluble powder for addition to drinking water or milk replacer, or combined with emulsifying agents to facilitate their administration as liquid drenches. Challenges with powder dosage forms include undesirable taste attributes and potential problems with keeping denser powders from separating and concentrating at the bottom of the feed trough. Quality attributes include blend uniformity, impurities, and moisture.

Granules: This dosage form consists of powder particles that have been granulated with other excipients to form larger particles, usually 2–4 mm in diameter. Granulation enhances ease of blending (e.g., with other excipients) and blend uniformity.

Types of Dosage Forms: Medicated Feed

Type A medicated article consists of an API with or without a carrier (e.g., calcium carbonate, rice hull, corn, gluten) and with or without inactive ingredients. The Type A medicated article may be used to manufacture another Type A, or a medicated article that has been diluted with additional feed (Type B or a Type C). The Type A medicated article is manufactured by mixing or granulating excipients to the API. The API can be synthesized chemically or produced by a fermentation reaction. Adding excipients enhance the uniformity of the mix, prevent segregation of the drug, and prevent segregation during transportation. Excipients can also be added to prevent dust formation during the mixing and to stabilize the drug in medicated feed.

Types of Dosage Forms: Biomass Products

The FDA Guidance for Industry, *#216 Chemistry, Manufacturing, and Controls (CMC) Information—Fermentation-Derived Intermediates, Drug Substances, and Related Drug Products for Veterinary Medicinal Use* can be used as a general guide for the fermentation process used in biomass production.

Biomass APIs are an unpurified fermentation product. The contents of the fermentation vessel are dried to produce the biomass drug substance. Characterization of an API typically addresses the active molecule and impurities, which could include:

- the organism used in the fermentation, other metabolites produced by the organism, and components of the fermentation media;
- structural elucidation, which typically includes elemental analysis, mass spectrometry, infrared spectroscopy, ultraviolet spectroscopy, nuclear magnetic resonance spectroscopy, X-ray crystallography, and/or other appropriate tests. When the active ingredient is a mixture of related molecules, structural elucidation of isolated and purified individual components may be appropriate;
- physiochemical properties such as optical rotation, solubility profile, dissociation constant, and other properties that may affect performance of the finished product;
- biological activity, which includes drug potency and homogeneity;
- identity of the organism (genus, species, strain) and its source;
- identification of all metabolites with antimicrobial activity or toxicity. This may be determined through studies or scientific literature e.g., the "fingerprint" of the biomass.

Types of Dosage Forms: Controlled Internal Drug Release System

Controlled Internal Drug Release System (CIDR) is an intravaginal insert that is typically used in dairy cattle, goats, and sheep. The CIDR is a T-shaped device with flexible wings that collapse to form a rod which can be inserted into the vagina with an applicator. On the end opposite to the wings of the insert is a tail that is attached to facilitate removal of the device. The backbone of the CIDR is a nylon spine covered by a progesterone-impregnated silicone skin. The rate of progesterone release is influenced by the surface area of the implant and by the drug load. Upon its insertion, blood progesterone concentrations rise rapidly, with maximal concentrations reached within an hour. Progesterone systemic concentrations are maintained at a relatively constant level throughout the 7 days during which the insert is resident within the vagina. Upon its removal, systemic progesterone concentrations rapidly decline (Rathbone et al., 2002).

Types of Dosage Forms: Liquid or Semisolid Dosage Forms

Parenteral products: The formulation and manufacture of injectable dosage forms involves a different set of considerations than that associated with oral products. The need for microbiological stability is the primary difference. Vials of injectable formulations may be concluded to be sterile upon release for marketing, but once the stopper is punctured, sterility can no longer be assured. Multiuse injection products must therefore be formulated with sufficient concentrations of bacteriostatic/fungistatic agents such as methylparaben to avoid growth of microorganisms in the remaining vial contents.

As with solid pharmaceuticals, injections may be formulated as either IR or MR dosage forms. Since the in vivo residence time of injectable formulations are not constrained by GI transit times, there are few limitations on the duration of drug release from these dosage forms. To achieve the desired time release characteristics, formulators can manipulate product physical properties such as viscosity and particle size.

One of the critical considerations when manufacturing parenteral dosage forms is the need to insure product sterility. Selection of an appropriate process necessitates an understanding of the potential chemical reactions that can occur. Accordingly, the strengths and limitations of the various sterilization processes depend on physical aspects unique to the type of pharmaceutical. In this regard, it is important to note that sterilization drives design of manufacturing processes, facilities, and formulation of sterile injections.

Common sterilization techniques used for parenteral products include:

- Sterile filtration/aseptic processing: sterilization is achieved by passing the solution through a filter designed to retain bacteria.
- Terminal sterilization: product sterilization after the product is already packaged. Types of terminal sterilization processes include:
  - Moist heat terminal sterilization: Terminal sterilization by the use of an autoclave. Terminal moist heat sterilization is often preferred for aqueous solutions.
  - Radiation terminal sterilization: Products are conveyed to an ionizing radiation source, ensuring that each unit receives the amount of radiation exposure necessary to kill the microbes within the unit. Gamma irradiation, for example, kills bacteria by inducing the formation of free radicals that damage nucleic acids within the microorganisms (Savjani et al., 2012). This method may be more appropriate for heat-labile materials.

Common types of injectable formulations include:

- injectable aqueous solutions;
- injectable aqueous suspensions;
- injectable organic solutions/suspensions;
- lyophilized (freeze-dried) powders for injection.

Analytical testing of injection dosage forms may include the following parameters.

- Appearance/description: In addition to the general color, opacity, and appearance of the product, the existence of *visible* particulate matter should be noted. Subvisible particulates are enumerated in the Particulate Matter Test, described below.
- Identification
- pH
- Viscosity (if appropriate)
- Assay for active ingredient
- Assay for preservatives (if appropriate): For multiuse products, a liquid or gas chromatography method may be used to detect levels of antimicrobial preservatives. The manufacturer must demonstrate that the limits for concentrations of preservatives still represent levels that effectively inhibit microbial growth. This test is omitted if the product is single-use only.
- Water: A water test is generally only appropriate for lyophilized powder or nonaqueous injections.
- Impurities
- Dissolution/drug release (if appropriate): If an injection is considered immediate release, this test is typically omitted from the testing battery. For MR injections, a manufacturer may develop a test similar to those used for oral dosage forms according to USP guidelines, but this is not practical in cases where the release from the product in vitro extends more than a few days. Often, in vitro dissolution or drug release tests must be "accelerated" by the use of organic solvents or by the use of dissolution media that allow for the completion of the test in a reasonable period of time.
- Particulate matter (IV use): This test measures the number of subvisible particles, specifically those 25 μm in diameter or less, and is different from the Appearance/ Description visible check for particles, described above. These tests are performed using light obscuration (laser scattering) or microscopy. Veterinary products that are not intended for IV use are exempt from this testing.
- Bacterial endotoxins: Gram-negative bacteria present during the manufacturing process release lipopolysaccharides, known as endotoxins, upon the death of the bacteria (Booth, 2001). Endotoxins are antigenic to most target species and cannot be completely eliminated by the most common sterilization techniques. USP Chapter <85> (USP, 2009b) describes tests to measure endotoxin levels (with results expressed either as Endotoxin Units (EU) or as International Units (IU)). Endotoxin limits for products administered by IM, SC, or IV routes historically have been based on the rabbit endotoxin sensitivity of about 5 EU/kg body weight divided by the dose of the injection per kilogram body weight (Rahman et al., 2014). Although it is recognized that each target animal may differ in its sensitivity to endotoxins, unique endotoxin limits have not been developed for individual species.
- Sterility: Tests for sterility usually follow one of the procedures described in USP Chapter <71> (USP, 2009a). In general, it is a requirement that all injection dosage forms be free of microbial contamination (i.e. sterile) before being marketed.

Types of Dosage Forms: Topical Dosage Forms

Topical products may be formulated as solutions, suspensions, ointments, gels, creams, emulsions, or aerosol. Unlike transdermal formulations, these products are not intended to be systemically absorbed. The location of delivery can be the skin, the mammary gland, the eyes, or the ears. The location of the application dictates the appropriate excipients to insure that the API reaches and is retained within the site of action. One of the challenges encountered with these products is that systemic drug concentrations (e.g., blood level profiles) cannot be used to evaluate product performance. As a result, the formulation chemist needs to rely upon in vitro and physicochemical tests to evaluate the impact of formulation and manufacturing method on product CQAs. In turn, without extensive clinical trials and/or in situ model studies, allowable deviations in product physicochemical characteristics will be very difficult to define (Teng et al., 2009).

Types of Dosage Forms: Transdermal Drug Delivery

Formulating the API so that it penetrates protective barriers such as skin can be a significant challenge. A number of complex systems have been developed to accomplish this goal including patches, ointments, suspensions, lotions, plasters, pastes, and dressings. Within this textbook, Chapters 2 and 47 discuss this topic further.

Manufacturing Process

The manufacturing process can have as great an influence on drug product quality and performance as the formulation. For that reason, the manufacturing process needs to be considered both from the perspective of the dosage form, batch size, and physicochemical properties of the drug and its excipients. As mentioned under our discussion of lubricants, something as simple as blending time or the order of excipient addition can make the difference between products that exhibit the desired in vivo characteristics versus those failing to exhibit the targeted quality attributes.

Wet/dry granulation: The tablet manufacturing process can be classified as granulation (wet or dry granulation) or direct compression. Granulation is a process that causes an increase in particle size, thereby improving the flow, density, and compressibility of the powder (API and excipients). Granulation can be achieved by using a binder solution (wet granulation) or a dry granulation (without the addition of a binder solution).

Wet granulation is the most commonly used method to manufacture veterinary tablets. Wet granulation (low shear, high shear, fluid bed, extrusion, and spheronization process of converting material into spheres) is a process of using a liquid binder (usually a hydrophilic colloid) to lightly agglomerate the powder mixture. This reduces the interparticulate friction and improves the fluidity and compressibility of the powder. The binder, which is distributed over large surface areas, acts as glue to overcome the lack of cohesiveness of the original API and the fillers. Wet granulation also improves the blend uniformity for soluble low-dosage drugs and is an effective technique to improve the dissolution rate of hydrophobic compounds. The quality of this technique is generally governed by the physicochemical properties of the powder and/or granulation from which tablets are composed. Wet granulation may not be suitable for an API that is sensitive to humidity or temperature.

Dry granulation (roller compaction or slugging) is a process that creates granules by compaction of the powder blend under low pressures. This process often results in ribbons that are subsequently milled and screened to form granules of the desired particle size. The advantage of dry granulation is the absence of heat and moisture. However, it can lead to dust formation and may not be as efficient as wet granulation in terms of insuring the uniformity of the API content in the resulting granules.

Direct compression: Direct compression is the tableting of ingredients in the absence of a preliminary granulation step. This process avoids many of the problems associated with wet and dry granulation and is best used for formulations that exhibit good flowability, compactibility, and compressibility. However, the product generated by direction compression methods is highly dependent on the intrinsic physical properties of the raw materials (especially fillers). Any variability in the quality of the raw materials may affect the flow and compression characteristics, causing the direct compression to be challenging. In an effort to overcome this hurdle, some excipients are now available to facilitate direct compression (e.g., fast flow lactose, dicalcium phosphate dibasic, microcrystalline cellulose). These excipients are manufactured consistently to assure their physical forms (e.g., particle size, particle shape), thereby facilitating improved formulation flowability and compressibility.

Extrusion: Extrusion processes can be categorized as either ram extrusion or screw extrusion. Either technique is well suited for the precision extrusion of highly valuable materials. Process control monitoring includes zone temperature, the monitoring of torque, drive amperage, and pressure and melt viscosity. Temperatures are normally controlled by electrical heating bands and monitored by thermocouples.

Roller compaction: Recently, dry granulation using roller compaction has grown in popularity, as the process is economical, energy efficient, easily automated, and suitable for drugs that are sensitive to heat and moisture (Kona et al., 2014). In roller compaction, the powder blend is compressed and compacted between two counter-rotating rollers resulting in ribbons, which when milled produce granules of the desired size (Kostewicz et al., 2014). Following the use of roller compaction, the resulting granules are mixed with lubricant and/or other excipients and finally compressed into the tablets.

Slugging: Slugging is used to compress the formulation into relatively large tablets that are subsequently milled and screened to attain the desired size granules. The resulting granules are blended with lubricant and/or any other excipients and then finally compressed into tablets.

Tableting processes: The size and speed of tableting machines (presses) can vary, but their general operating principles are the same. Tableting processes typically use a powder blend or granulation. The powder blend or granulation is added to a hopper, which then flows in a controlled manner into dies. Above and below each die are punches that create the compression pressure necessary to form the tablet into the appropriate shape. Tablet shape is determined by the geometry of the die. Following compression, the newly formed tablets are ejected from the press and the process repeats.

Factors Influencing Product Dissolution

Upon examination of the attributes of the dosage forms described in this chapter, it is evident that the ability of the drug to dissolve in and diffuse through biological fluids is an essential component of product performance. The fundamental issue is developing an understanding of the physicochemical properties of the API and how to adjust the formulation so as to accommodate the critical factors influencing in vivo product performance. With respect to product dissolution, the critical factors can be identified in the Noyes–Whitney equation (Equation 5.9).

$$\frac{dC}{dt} = K \times S\,(Cs - C) \tag{5.9}$$

Where

dc is the change in concentration of drug in solution
C is the concentration of drug in solution
dt is the change in time (expressed in the units of interest)

Cs is the solubility of the drug in the media
S is the surface area of the solid drug
K is a constant describing the diffusion of the drug in the media

This equation can be further modified to include terms pertaining to diffusion layer thickness, particle density, and particle shape. These additional terms have been incorporated into in silico physiologically based pharmacokinetic models to predict in vivo drug dissolution (Lennernäs et al., 2014; Brouwers et al., 2009).

Some techniques to increase product dissolution rate include reducing the particle size of the drug to increase the surface area, adding excipients to form micelles and enhance solubility in the diffusion layer thickness, or use of a highly water-soluble salt of the parent drug substance. Changes in saturation solubility are now being incorporated as mechanisms for achieving "supersaturation" whereby drugs that would typically precipitate in the gastrointestinal tract now remain in solution for a longer duration, thereby facilitating drug absorption (Waterman et al., 2006). By combining information on the drug absorption capability of the various intestinal segments, drug physicochemical properties (including pKa and aqueous solubility) and formulation dissolution rate, we can predict the likely in vivo blood level profiles.

Putting it All Together: Product Quality Control

Efforts of the pharmaceutical scientist culminates in the manufacture of a product that provides the desired in vivo and in vitro release characteristics. Once a formulation and the corresponding manufacturing method is finalized and that product is determined to exhibit the desired clinical and physicochemical attributes, there is the need to insure that all future batches will perform in a likewise manner. Quality cannot be tested into a product; rather, it is the culmination of product/process understanding, in-process controls and adhering to cGMPs that provide a greater assurance of drug quality. Many of the parameters that we discuss here become translated into batch release specifications (i.e., test results that must be met in order to release the batch or lot for public distribution).

Conclusion

The development of a pharmaceutical formulation that succeeds in meeting the desired rate and extent of in vivo drug exposure is possible only through an understanding of the physicochemical attributes of the API. In turn, the appropriate dosage form and excipients need to be defined. However, as we have emphasized, a drug recipe is certainly not sufficient to insure achieving the desired drug product performance. The order in which ingredients are added, the kinds of equipment used, the quality of the excipients, and the ability to understand and achieve tight control over the manufacturing process are no less important than the formulation. Appreciating these nuances in the principles of pharmaceutics lends not only to the development of high-quality safe and effective dosage forms but also allows for an assurance of each production batch meeting consumer expectation and an understanding of the veterinarian as to challenges that may be encountered when a specific product is administered to the animal patient.

Acknowledgments

The authors wish to acknowledge useful discussions with Drs. Gregory Hunter and Ramzy Labib during the preparation of this chapter.

Section 2

Drugs Acting on the Autonomic Nervous System

6

Introduction to the Autonomic Nervous System and Autonomic Pharmacology

Joshua A. Rowe, Rose M. McMurphy, Barbara J. Lutjemeier, and Michael J. Kenney

Introduction

The autonomic nervous system (ANS) includes afferent, central, and efferent components. The efferent component is the general visceral efferent (GVE) system and is subdivided into two primary branches, the sympathetic nervous system (SNS) and the parasympathetic nervous system (PSNS). More recently, the enteric nervous system is considered a functional component. The ANS plays a critical role in regulating processes required for maintaining physiological homeostasis and responding to acute stressors. Numerous physiological functions are regulated by the ANS including, but not limited to: regulation of heart rate and cardiac contractility; visceral and cutaneous blood flow distribution; gastrointestinal motility and digestion; and urogenital processes. It is virtually impossible to consider physiological regulation without integrating the roles of sympathetic and parasympathetic neural mechanisms into a functional overview, as summarized in the *Primer on the Autonomic Nervous System* (Hamill and Shapiro, 2004):

> The autonomic nervous system (ANS) is structurally and functionally positioned to interface between the internal and external milieu, coordinating bodily functions to ensure homeostasis (cardiovascular and respiratory control, thermal regulation, gastrointestinal motility, urinary and bowel excretory functions, reproduction, and metabolic and endocrine physiology), and adaptive responses to stress (flight or fight response). Thus, the ANS has the daunting task of ensuring the survival and the procreation of the species.

For the most part, physiological processes regulated by the ANS are not under voluntary control and are essential for maintaining physiological regulation under basal or resting conditions, as well as in response to various forms of physical or emotional stress. Changes in the level of afferent and efferent activity in sympathetic and parasympathetic nerves occur primarily independent of conscious or voluntary control, thereby providing the derivation for the name autonomic nervous system (from the Greek: *auto* = self; *nomos* = law).

Sympathetic Nervous System

Sympathetic nerves originate from cell bodies in the intermediolateral cell column of the thoracic (T) and lumbar (L) sections of the spinal cord, synapse in ganglia (more anatomical detail is presented later in this chapter), and project to a wide array of targets (Figure 6.1). The level of activity in sympathetic nerves is regulated at multiple levels of the brain, including hypothalamic and brainstem sympathetic neural circuits (Figures 6.1 and 6.2). The majority of sympathetic nerves demonstrate a tonic or basal level of activity, characterized by the presence of bursts of activity (Claassen et al., 1996). Figure 6.3A shows original traces of directly recorded nerve discharge bursts from four sympathetic nerves (renal, adrenal, splanchnic, lumbar). Direct recordings of sympathetic nerve activity provide an output measure of central sympathetic neural circuits. Changing the level of activity in peripheral sympathetic nerves, by either increasing or decreasing the level of sympathetic nerve discharge (SND), is a primary means by which the SNS regulates physiological function (Kenney, 2014; Kenney et al., 2014). For example, heat stress or hyperthermia increases the level of visceral SND (Figure 6.3B), thereby mediating a redistribution of blood flow away from visceral organs to cutaneous vascular beds. On the other hand, acute increases in arterial blood pressure activate the arterial baroreceptor reflex which abruptly reduces SND (Figure 6.3C), a physiological response that contributes to returning blood pressure to normal levels. In this example (Figure 6.3C) blood pressure was increased by the intravenous administration of the adrenergic agonist drug, phenylephrine hydrochloride, which will be discussed in more detail in Chapter 7.

In many contexts the primary understanding of SNS regulation has focused on the activation of this nervous system as a unit, as in response to critical emergencies

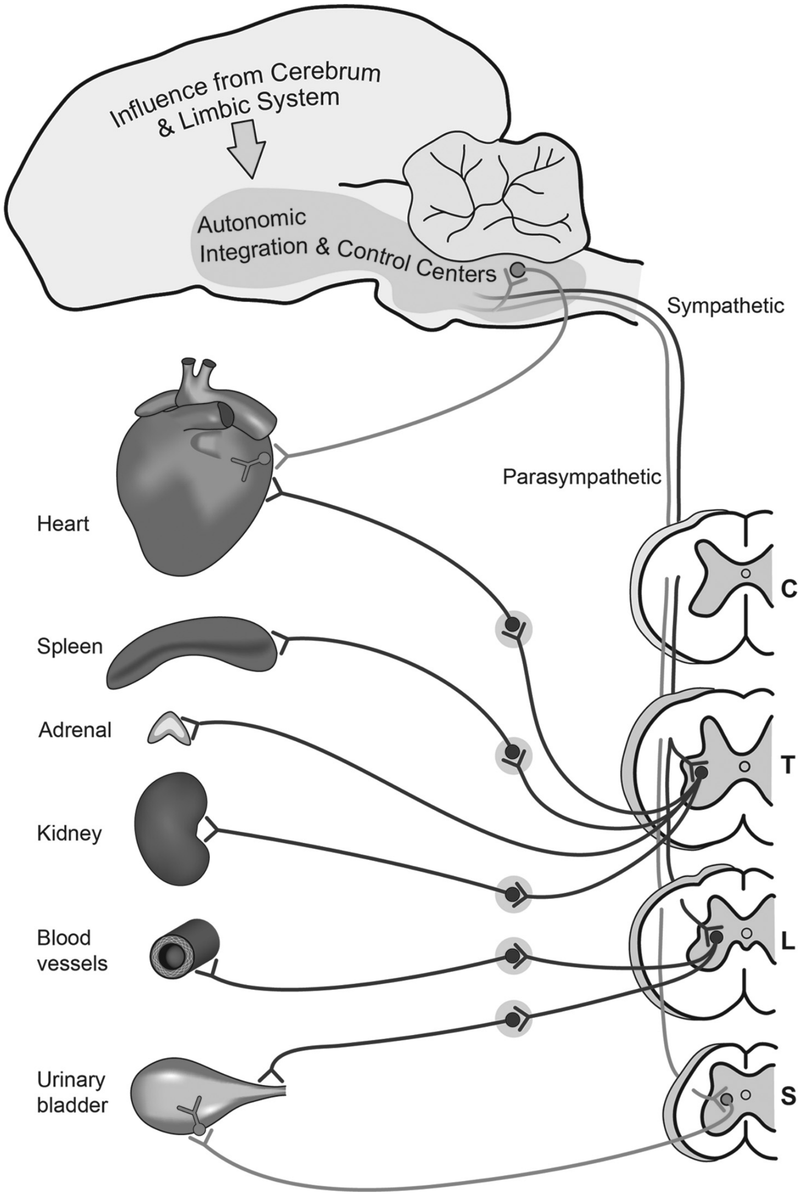

Figure 6.1 Schematic diagram highlighting anatomical features of the autonomic nervous system. Sympathetic preganglionic neurons originate from cell bodies located in the intermediolateral cell column of the thoracic (T) and lumbar (L) sections of the spinal cord, synapse in ganglia located outside the spinal cord, and postganglionic neurons project from the sympathetic ganglia to a wide array of targets. The chromaffin cells of the adrenal medulla are analogous to ganglionic neurons and are innervated by sympathetic preganglionic neurons. Efferent activity in sympathetic nerves is regulated by various integration and control centers located at multiple levels of the supraspinal neuraxis (identified as Autonomic Integration and Control Centers). Presympathetic neurons from these hypothalamic and brainstem sites project to the thoracic and lumbar spinal cord sites where the sympathetic preganglionic cell bodies are located. Parasympathetic preganglionic neurons originate from cell bodies located in brainstem nuclei and in the intermediolateral cell column of the sacral (S) spinal cord. Parasympathetic preganglionic neurons are innervated by nerve endings of preparasympathetic neurons whose cell bodies are found in supraspinal nuclei. Many parasympathetic preganglionic neurons terminate and synapse in intramural ganglia located within the innervated target organs, or in ganglia located outside but near the innervated target organs. C, cervical spinal cord.

or to elicit the “fight-or-flight” response. In these conditions, SNS activation mediates increased heart rate and cardiac contractility, vascular vasoconstriction in skin and viscera with shunting of blood flow to skeletal muscles, hepatic glycogenolysis, bronchiolar and pupillary dilation, and contraction of the spleen. This physiological response profile is mediated by the combined activation of peripheral sympathetic nerves innervating specific target organs (e.g., heart, blood vessels) and the adrenal medulla. This prominent activation state led to the concept that the SNS acts as a unit. However, it is now well-understood that a fundamental regulatory strategy of the SNS involves selectively controlling the level of activity in nerves innervating different targets in response to a number of physiological conditions (i.e., nonuniform regulation of sympathetic nerve activity). For example, acute cold stress or hypothermia increases the level of activity in nerves innervating cutaneous blood vessels but reduces the level of activity in nerves innervating the kidney, providing the neural substrate for reducing blood flow to the periphery and increasing visceral organ blood flow. The ability to selectively regulate the level of activity in sympathetic nerves innervating specific targets provides the neural substrate for producing highly specific physiological response profiles. Physiological responses of selected organs and effector tissues elicited by activation of efferent sympathetic nerves are summarized in Table 6.1. Specific receptor classes and types involved in mediating SNS-induced physiological responses are included in Table 6.1 and are introduced

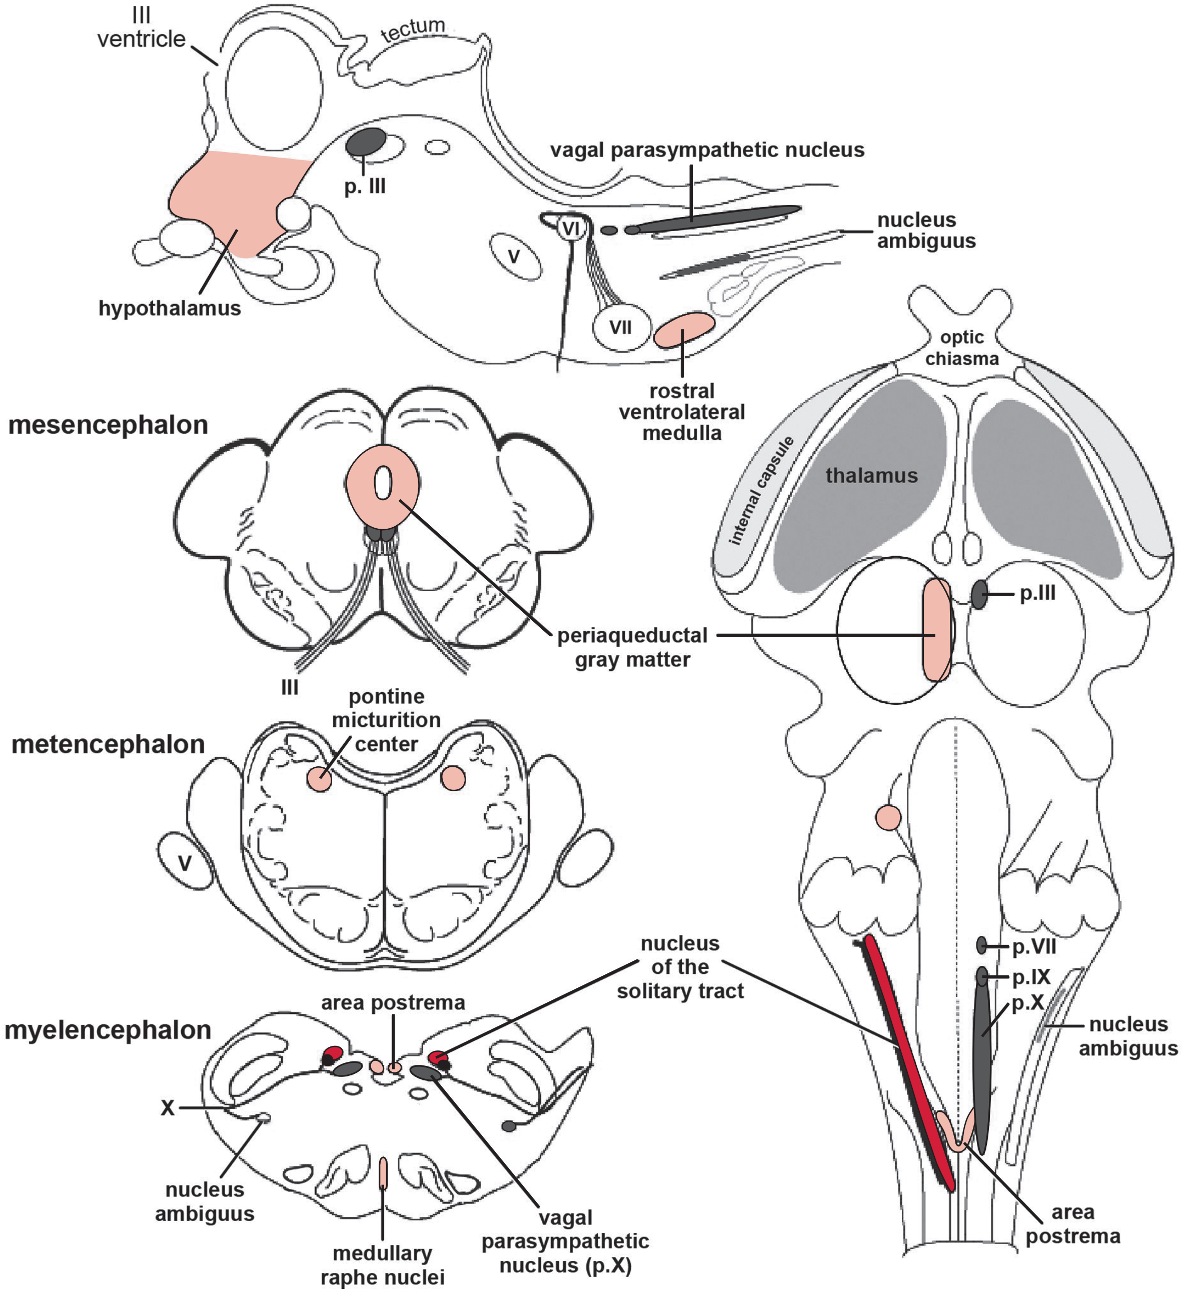

Figure 6.2 Selected autonomic nuclei and centers are shown in transverse (left), dorsal (right), and midsagittal (top) views. Components depicted in light red represent autonomic integration, relay, and/or control centers. The nucleus of the solitary tract, an important visceral sensory nucleus, is red. Brainstem preganglionic parasympathetic nuclei (p.) are shown in dark gray (including a portion of the nucleus ambiguous which provides cardiac visceral efferent neurons). Bilateral structures are shown on one side only in the dorsal view and not all structures are represented in each view to minimize clutter. The hypothalamus is the principle integration and control center of the autonomic nervous system and contains numerous nuclei, which are involved in the regulation of autonomic function. The periaqueductal gray matter surrounds the mesencephalic aqueduct and serves (among other functions) as a relay for visceral control signals from the hypothalamus to hindbrain nuclei. The pontine micturition center (just one of several autonomic control centers in the brainstem which control visceral functions) contains neurons that project to the lumbosacral spinal cord where they excite sacral preganglionic parasympathetic neurons which cause contraction of the urinary bladder wall and inhibit neurons to urinary sphincters (lumbar preganglionic sympathetic and sacral somatic neurons). The rostral ventrolateral medulla and medullary raphe nuclei are major sites of presympathetic neurons that project to preganglionic sympathetic neurons in the thoracolumbar spinal cord. The area postrema (just one of several circumventricular organs which are located in close proximity to the ventricular system of the brain and lack a blood–brain barrier) detects emetic agents in the blood and projects to hindbrain nuclei responsible for controlling emesis; other circumventricular organs (not shown) are likewise susceptible to direct chemosensory stimulation by blood-borne agents and are involved in other aspects of neuroendocrine and autonomic function. Source: Adapted from Fletcher and Brown, 2010.

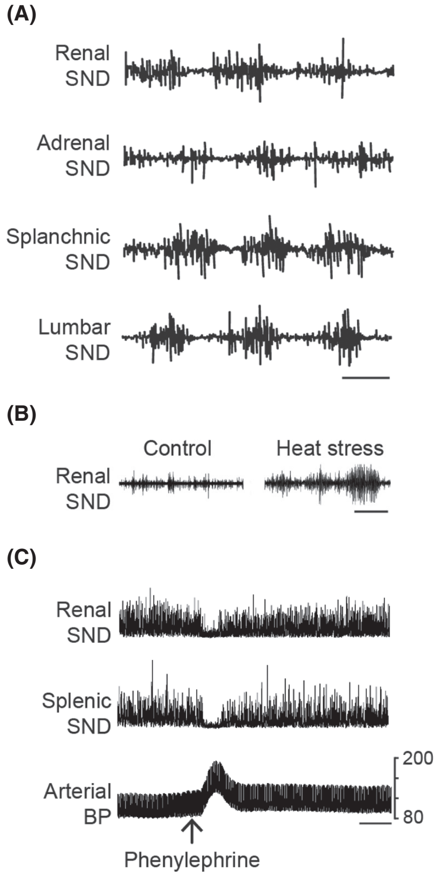

Figure 6.3 **(A)** Traces of sympathetic nerve discharge (SND) recorded under basal conditions from renal, adrenal, splanchnic, and lumbar nerves. Note that at rest sympathetic nerves are characterized by the presence of a tonic level of activity. Horizontal calibration is 100 ms. Source: Adapted from Claassen et al., 1996. **(B)** Traces of renal SND recorded under control conditions and during heat stress. Renal SND was increased from control levels during the period of acute heat stress. Horizontal calibration is 250 ms. Source: Adapted from Kenney, 2014. Reproduced with permission of Elsevier. **(C)** Traces of discharges from renal and splenic sympathetic nerves recorded before, during, and after an acute increase in arterial blood pressure produce by the intravenous administration of the α-adrenergic receptor agonist, phenylephrine hydrochloride. The acute increase in arterial blood pressure and subsequent activation of the arterial baroreceptors elicited a reflex-mediated inhibition of SND. Horizontal calibration is 15 s. later in this chapter and considered in more detail in Chapter 7.

Parasympathetic Nervous System

Parasympathetic nerves originate from cell bodies in the brainstem and sacral sections of the spinal cord, and synapse in ganglia (more anatomical detail is presented later in this chapter). The level of activity in parasympathetic nerves is regulated by multiple areas in the brain (Figures 6.1 and 6.2). Parasympathetic nerves innervating many target organs are tonically active and changing the level of activity in peripheral parasympathetic nerves in response to specific physiological stimuli is a primary mechanism by which the PSNS regulates physiological function. Figure 6.4 shows directly recorded cardiac vagal parasympathetic nerve discharge under basal conditions, and in response to an experimentally induced activation of the baroreceptor reflex, which produced an increase in the level of cardiac vagal nerve activity and an associated reduction in heart rate (Simms et al., 2007). The primary functional profile elicited by activation of the PSNS includes initiating and sustaining energy conservation and homeostasis during periods of relative physiological quiescence. In general, increasing the level of activity in parasympathetic nerves reduces heart rate, stimulates gastrointestinal secretions and peristalsis, contracts the body of the urinary bladder, and modulates immune function. Physiological responses of selected organs and effector tissues elicited by activation of efferent parasympathetic nerves are summarized in Table 6.1. Specific receptor classes and types involved in mediating PSNS-induced physiological responses are included in Table 6.1, and are introduced later in this chapter and considered in more detail in Chapter 7.

Many organs and tissues are innervated by both the sympathetic and parasympathetic arms of the ANS, and these targets are described as receiving dual ANS innervation (e.g., heart and urinary bladder in Figure 6.1). In many instances physiological responses produced by activation of parasympathetic or sympathetic nerves to a target tissue or organ that receives dual ANS innervation are functionally antagonistic. That is, if activation of one arm of the ANS inhibits a specific physiological function then activation of the other arm enhances the function. For example, stimulation of cardiac sympathetic nerves increases heart rate whereas activation of cardiac parasympathetic nerves reduces heart rate. However, the presence of a dual ANS innervation to a specific target does not indicate that the physiological function of that target is balanced to the same degree for each arm of the ANS. On the contrary, the basal physiological function of many organs is weighted towards either PSNS or SNS regulation, an effect that is species dependent and can vary depending on the specific physiological situation or pathophysiological state (Box 6.1 Case study). For example, the gastrointestinal system is regulated by the enteric nervous system, along with the SNS and the PSNS. Activation of parasympathetic nerves innervating the gastrointestinal tract and administration of drugs that mimic the PSNS stimulate gastrointestinal functions, whereas it is generally considered that the SNS exerts more of a modulatory effect on gastrointestinal function consistent with the fact that sympathomimetic drugs are not prominently used as GI inhibitory agents

Table 6.1 Physiological responses of selected organs and effector tissues produced by activation of efferent sympathetic (sympathetic stimulation) and parasympathetic (parasympathetic stimulation) nerves. Specific receptor classes and types involved in mediating the physiological responses are included for sympathetic (adrenergic receptors; α and β) and parasympathetic (muscarinic receptors; M) stimulation. Stimulation of sympathetic nerves innervating the adrenal medulla mediates secretion of epinephrine (EPI), an effect involving activation of nicotinic neural (N_N) receptors

Organs/effector tissues	Sympathetic stimulation	Receptor	Parasympathetic stimulation	Receptor
Eye				
Radial muscle, iris	Pupillary dilation	α_1		
Sphincter muscle, iris			Pupillary constriction	M_3, M_2
Ciliary muscle	Slight relaxation	β_2	Contraction	M_3, M_2
Glands of head				
Lacrimal	↑ Secretion (minor effect)	α_1	↑↑ Secretion (major effect)	M_3, M_2
Salivary	↑ Secretion (minor effect)	α_1	↑↑ Secretion (major effect)	M_3, M_2
Lungs				
Bronchiolar smooth muscle	Bronchiolar dilation	β_2	Contraction	$M_2 = M_3$
Heart				
Sinoatrial node	↑ Heart rate	$\beta_1 > \beta_2$	↓ Heart rate	$M_2 >> M_3$
Atria	↑ Contractility/conduction	$\beta_1 > \beta_2$	↓ Contractility/conduction	$M_2 >> M_3$
Atrioventricular node	↑ Automaticity/conduction	$\beta_1 > \beta_2$	↓ Conduction	$M_2 >> M_3$
Ventricle	↑ Contractility/conduction	$\beta_1 > \beta_2$	↓ Contractility	$M_2 >> M_3$
Blood vessels (arteries and arterioles)				
Coronary	Constriction; dilation	α_1, α_2; β_2		
Pulmonary	Constriction; dilation	α_1; β_2		
Skin and mucosa	Constriction	α_1, α_2		
Skeletal muscle	Constriction; dilation	α_1; β_2	Dilation (not due to parasympathetic stimulation)	M_2
Abdominal viscera	Constriction; dilation	α_1; β_2		
Gastrointestinal tract				
Motility	↓ Motility	α_1, α_2, β_1, β_2	↑ Motility	$M_2 = M_3$
Sphincters	↑ Tone	α_1	↓ Tone	M_3, M_2
Secretion	Inhibition	α_2	Stimulation	M_3, M_2
Urinary bladder				
Detrusor muscle	Relaxation	β_2	Contraction	$M_3 > M_2$
Sphincters	Contraction	α_1	Relaxation	$M_3 > M_2$
Sex organs				
Male	Ejaculation	α_1	Erection	M_3
Female			Erection

Autoreceptor			Inhibition of ACh release	M_2, M_4
Heteroreceptor	Inhibition ACh release	α_2		

in clinical conditions. Therefore, the gastrointestinal system receives a dual ANS innervation and the physiological responses mediated by these nervous systems are functionally antagonistic. However, the fundamental physiological regulatory processes are weighted towards PSNS dominance. Moreover, in some cases the dual SNS and PNSN innervation to a specific tissue may produce similar yet not identical responses. For example, the salivary glands receive a dual ANS innervation, although activation of the SNS and PSNS do not produce

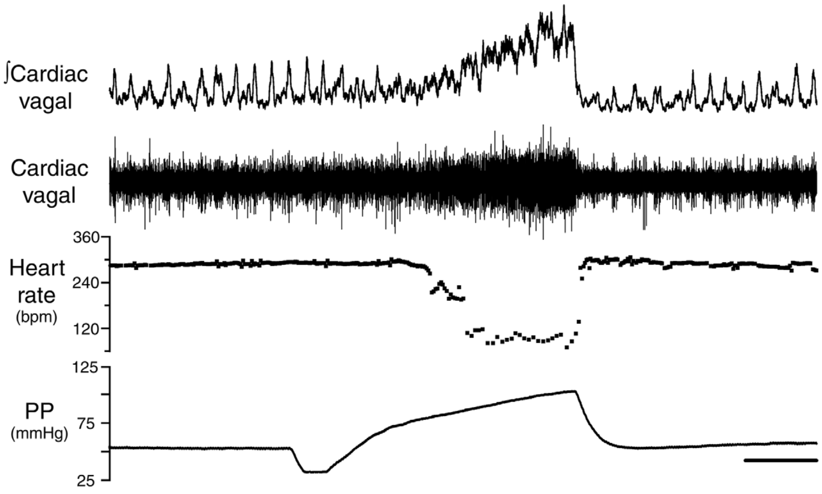

Figure 6.4 Traces of cardiac vagal nerve activity and heart rate recorded before, during, and after activation of the baroreflex produced by experimental manipulation of aortic perfusion pressure (PP). Note the presence of a tonic level of cardiac vagal nerve activity, the increase in vagal nerve activity in response to baroreflex activation, and the expected reflex-mediated reduction in heart rate in response to the increase in cardiac vagal nerve activity. Source: Adapted from Simms, 2007. Reproduced with permission of John Wiley & Sons.

functionally antagonistic responses. Activation of the SNS innervation to the salivary glands produces secretion of amylase and a viscous salivary fluid (secondary to activation of α-adrenergic receptors) whereas activation of PSNS innervation to the salivary glands produces a watery salivary fluid.

The ANS also contains extensive afferent (sensory) components that provide neural information regarding the internal physiological environment. The peripheral afferent components, namely the general visceral afferent (GVA) system, generally utilize similar nerve pathways as the efferent components. For example, the vagus nerve and its branches are comprised of approximately 80% afferent fibers (sensory) and 20% efferent fibers (DuBois and Foley, 1936). Afferent pathways conveying peripheral sensory information ultimately project to multiple supraspinal sites, including the hypothalamus and brainstem (e.g., the nucleus of the solitary tract). Integration of neural information at central sites can modulate the level of efferent activity in sympathetic and parasympathetic nerves.

It has often been considered that the ANS operates rather independently of other adaptive systems. However, the functional repertoire of the ANS now includes an important role for both arms of this nervous system in regulating and integrating processes between

Box 6.1 Case Study

An 8-year-old, female, spayed mixed breed dog was presented for acute onset of vomiting and lethargy. Laboratory data were consistent with mild dehydration. Vomiting continued despite treatment with intravenous fluid and antibiotics over the next 24 hours for presumed gastritis. Abdominal radiographs and ultrasound were negative for gastrointestinal foreign body or obstruction. No peristalsis was evident on ultrasound. The vomiting subsided but the patient became progressively more lethargic and unable to ambulate more than a few feet. The patient refused to eat. Fecal incontinence was present secondary to decreased anal sphincter tone. Although the dog was initially able to urinate, the volume of urine she was able to expel progressively decreased over several days until she was unable to void. Photophobia developed and the pupillary light reflex became sluggish. An echocardiogram revealed an ejection fraction of only 14%. The heart rate remained near 85 beats per minute despite this low ejection fraction. A diagnosis of dysautonomia was made (Harkin et al., 2002; Harkin et al., 2009).

Dysautonomia is an idiopathic neurodegenerative disorder characterized by degeneration of neurons in ANS ganglia, which produces marked changes in the function of target organs innervated by the sympathetic and parasympathetic nervous systems (Harkin et al., 2002; Harkin et al., 2009). Due to the widespread innervation of the ANS to numerous tissues and organs, patients with dysautonomia present with alterations in multiple physiological systems, making this disease state difficult to diagnose. Changes in target function are generally manifested based on the usual predominance of sympathetic or parasympathetic tone to a given organ or tissue. For example, under basal conditions, function of the gastrointestinal tract is dominated by a predominance of parasympathetic nerve activity conveyed via the vagus nerve and manifested as enhanced gastrointestinal motility and activity. Therefore, ganglionic degeneration and loss of the PSNS innervation to the gastrointestinal tract is often characterized by reduced smooth muscle tone and motility in patients suffering from dysautonomia.

diverse physiological systems. For example, it is well-established that the ANS plays a role in mediating interactions between the nervous and immune systems, two adaptive systems that have generally been considered to function independently of each other (Kenney and Ganta, 2014).

Multiple experimental methods have been employed for assessing SNS and PSNS contributions to physiological states and pathophysiological conditions including: pharmacological activation or blockade of receptors associated with the sympathetic and parasympathetic nervous systems; molecular approaches involving genomic and proteomic analyses; direct recordings of afferent and efferent activity in sympathetic and parasympathetic nerves; and the use of multiple methods to analyze specific components of directly recorded nerve activity. The collective contributions of these studies have provided essential information regarding the anatomical framework and physiological mechanisms regulating ANS function, thereby providing the backdrop for understanding autonomic pharmacodynamics and the development of specific autonomic drugs.

Anatomy of the Autonomic Nervous System: Overview

The ANS contains supraspinal, spinal, and peripheral (afferent and efferent) components, and is characterized by distinctive anatomical frameworks. The efferent components of both branches of the ANS use chemical neurotransmitters for conveying information between nerve cells (e.g., transmission from preganglionic neurons to postganglionic neurons at ganglionic sites) and from postganglionic neurons to target cells and tissues. Chemical neurotransmission involves the release of small amounts of neurotransmitter molecules from nerve terminals into the synaptic space, diffusion of transmitters across the synaptic space, neurotransmitter molecules binding to specialized receptors (specific receptors are discussed in a subsequent section) located primarily at postsynaptic sites on cells innervated by the ANS, and the subsequent activation or inhibition of intracellular secondary messenger mechanisms. The presence of adrenergic, cholinergic, and nonadrenergic–noncholinergic (NANC) neurons provides the essential substrates for generating and sustaining a diverse array of physiological functions. A fundamental tenet for understanding autonomic pharmacology begins with considering specific anatomical components of the sympathetic and parasympathetic nervous systems, which are described separately in this section.

Sympathetic Nervous System

Multiple sites in the central nervous system (CNS), including forebrain, brainstem, and spinal neural circuits, regulate the level of sympathetic nerve activity (Figure 6.2). The hypothalamus is a principal integration and control center of the ANS. Neurons within hypothalamic nuclei (e.g., the paraventricular nucleus) receive afferent signals from a variety of sources and, in turn, dispatch efferent signals to primary autonomic centers in the brainstem, (e.g., the rostral ventrolateral medulla (RVLM) and the midline medullary raphe nuclei). The axons of brainstem neurons within these centers (i.e., presympathetic neurons) project to sympathetic preganglionic neurons in the spinal cord (the axons of neurons in select hypothalamic nuclei also project to preganglionic neurons directly).

The cell bodies of sympathetic preganglionic neurons are located in the intermediolateral cell column of thoracic and cranial lumbar spinal segments (providing the derivation for the thoracolumbar terminology of the SNS). As mentioned, they are innervated by nerve endings of presympathetic neurons whose cell bodies are located in supraspinal nuclei. Sympathetic preganglionic nerve fibers exit the spinal cord in association with thoracic and lumbar spinal nerves and many sympathetic preganglionic neurons terminate and synapse in paravertebral ganglia located bilaterally on each side of the spinal column (Figures 6.1 and 6.5). Other sympathetic preganglionic neurons terminate and synapse in ganglia that are located closer to target organs, the prevertebral ganglia. Postganglionic sympathetic neurons arise from paravertebral and prevertebral ganglia and project to target organs and tissues (de Lahunta and Glass, 2009; Dyce et al., 2010; Evans and de Lahunta, 2013). The primary neurotransmitter released from preganglionic neurons at sympathetic ganglionic sites is acetylcholine (ACh), and at these sites ACh primarily binds to and activates nicotinic receptors located on the dendrites of postganglionic sympathetic neurons (Figure 6.5). Sympathetic ganglionic nicotinic receptors are classified as nicotinic neural (N_N) receptors. Nerve fibers that synthesize and release ACh are classified as cholinergic fibers; therefore sympathetic preganglionic nerve fibers are described as cholinergic. Norepinephrine (NE) (noradrenaline) is the predominant neurotransmitter released from postganglionic SNS neurons at target organ sites. At these sites NE primarily binds to and activates adrenergic receptors (designated as α and β receptors, as in Figure 6.5). Nerve fibers that synthesize and release NE are classified as adrenergic (or noradrenergic) fibers. Some postganglionic SNS neurons release dopamine (identified as dopaminergic neurons, as in Figure 6.5), which is the immediate metabolic precursor to NE and is an important neurotransmitter in the peripheral vasculature and

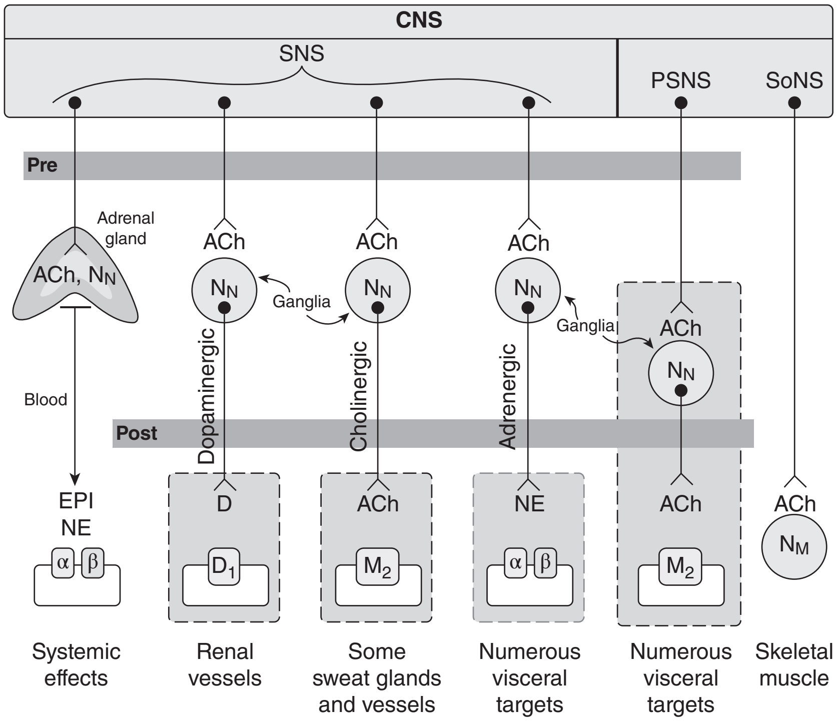

Figure 6.5 Schematic representation of the preganglionic and postganglionic anatomical relationships of nerves contained in the sympathetic nervous system (SNS) and the parasympathetic nervous system (PSNS). The anatomical substrate of somatic motor nerves (SoNS) is also shown. Only the primary neurotransmitters are shown. ACh is the neurotransmitter released at sympathetic and parasympathetic ganglia and at most parasympathetic neuroeffector junctions. Norepinephrine (NE) is the primary neurotransmitter released at adrenergic sympathetic neuroeffector junctions (see text for exceptions.) "Visceral targets" refers to smooth muscle, cardiac muscle, and glands. Note that some sympathetic postganglionic fibers release acetylcholine or dopamine rather than NE. The adrenal medulla, a modified sympathetic ganglion, is innervated by sympathetic preganglionic fibers and releases epinephrine and NE into the blood. ACh, acetylcholine; D, dopamine; EPI, epinephrine; M, muscarinic receptors; N, nicotinic receptors; NE, norepinephrine.

the CNS (Figure 6.5). Dopamine binds to and activates dopaminergic receptors (designated as D_1, as in Figure 6.5). The chromaffin cells of the adrenal medulla are analogous to ganglionic neurons, are innervated by preganglionic SNS fibers and contain N_N receptors, and synthesize and release epinephrine (EPI) and NE (Figure 6.5). A subgroup of postganglionic SNS neurons release ACh as a neurotransmitter (such as the sympathetic innervation to sweat glands in humans and the sympathetic innervation of skeletal muscle arteries in some species), and these fibers are classified as postganglionic sympathetic–cholinergic fibers (Figure 6.5). The ACh released from postganglionic sympathetic–cholinergic fibers binds to and activates muscarinic receptors (designated as M_2 in Figure 6.5).

Along with NE, cotransmitter molecules or substances are released from many postganglionic SNS fibers at target tissues and organs (Gourine et al., 2009; Burnstock, 2013; Herring, 2015; Ralevic, 2015). ATP has been identified as a cotransmitter along with NE in sympathetic nerves. NE and ATP may be stored in the same vesicles and released together, or may be stored in separate vesicles and regulated as individual entities. The relative contributions of NE and ATP in cell-mediated physiological responses depends on the specific target tissue, species, and neural stimulation parameters. ATP mediates responses via activation of purinergic receptors that are identified as adenosine (P1) receptors and P2X and P2Y receptors. Neuropeptide Y (NPY) can also be released with NE from sympathetic nerves and is an agonist at neurokinin receptors (e.g., Y_1 and Y_2). The primary physiological role of this peptide is to modulate sympathetic neurotransmission at both pre- and postsynaptic sites. Cotransmitters have an important signaling role in the cardiovascular, urogenital, and respiratory systems.

Parasympathetic Nervous System

Like the SNS, multiple CNS sites are involved in regulating efferent parasympathetic nerve outflow, although the integrative central mechanisms are not as thoroughly defined. The hypothalamus is involved in parasympathetic integration and control, and hypothalamic nuclei communicate with brainstem autonomic centers (e.g., the pontine micturition center). The axons of brainstem neurons within these centers (i.e., preparasympathetic neurons) project to parasympathetic preganglionic neurons in the brainstem and spinal cord. The axons of neurons in hypothalamic nuclei may also project to preganglionic neurons directly.

The cell bodies of parasympathetic preganglionic neurons are located in brainstem nuclei (e.g., the parasympathetic nuclei of the oculomotor, facial, glossopharyngeal, and vagus nerves, as well as the nucleus ambiguus) (Figure 6.2), and in the intermediolateral cell column of the sacral spinal cord (Figure 6.1). As mentioned, they are innervated by nerve endings of preparasympathetic neurons whose cell bodies are found in supraspinal nuclei. Preganglionic axons exit the brainstem with their respective cranial nerves (preganglionic parasympathetic axons from the nucleus ambiguus join the vagus nerve) whereas they exit the sacral spinal cord in association with sacral spinal nerves. The specific placement of preganglionic PSNS cell bodies in the brainstem and sacral spinal cord provides the derivation for the craniosacral terminology of the PSNS. Most parasympathetic preganglionic neurons terminate and synapse in intramural ganglia (terminal ganglia) located within the innervated target organs. Other preganglionic parasympathetic fibers terminate and synapse in ganglia (e.g., ciliary, pterygopalatine, submandibular, otic, and pelvic ganglia) located outside the innervated target organs or on ganglion cells that are characterized by a rather diffuse distribution of cells located near target organs (de Lahunta and Glass, 2009; Dyce et al., 2010; Evans and de Lahunta, 2013). Like the SNS, the primary neurotransmitter released from preganglionic neurons at parasympathetic ganglionic sites is ACh, and at these sites ACh primarily binds to and activates nicotinic receptors located on postganglionic parasympathetic neurons (Figure 6.5). Parasympathetic ganglionic nicotinic receptors are classified as N_N receptors. Postganglioinic parasympathetic neurons arise from parasympathetic ganglia and project to target cells, tissues, and organs. ACh is also the primary neurotransmitter released from postganglionic PSNS neurons at target organ sites, and at these sites ACh primarily binds to and activates muscarinic receptors (designated as M_2 receptors, as in Figure 6.5). As stated previously, nerve fibers that synthesize and release ACh are classified as cholinergic fibers, therefore both preganglionic and postganglionic parasympathetic neurons are cholinergic.

It is common that cotransmitters are released, along with ACh, from many postganglionic PSNS fibers at target tissues and organs (Gourine et al., 2009; Burnstock, 2013; Herring, 2015; Ralevic, 2015). Parasympathetic nerves innervating the urinary bladder release ATP as a cotransmitter and there is evidence that parasympathetic nerves supplying the salivary glands utilize vasoactive intestinal polypeptide as a cotransmitter. Similar to sympathetic nerves, ACh and specific cotransmitters may be stored in the same vesicles and released together, or may be stored in separate vesicles and regulated as individual entities. The relative contributions of ACh, ATP, vasoactive intestinal polypeptide, and other putative neurotransmitters and cotransmitters in cell-mediated physiological responses depends on the specific target tissue, species, and neural stimulation parameters.

Nonadrenergic–Noncholinergic Neurons

Some nerves that project to and innervate effector tissues and organs, generally at anatomical sites that are innervated by autonomic nerves, do not exhibit the histochemical characteristics of cholinergic or adrenergic fibers. These neurons are classified as nonadrenergic–noncholinergic (NANC) fibers. Many of the same molecules/substances identified as cotransmitters in ANS nerves also play a role as neurotransmitters released from NANC nerve endings (e.g., ATP, NPY) (Gourine et al., 2009; Burnstock, 2013; Herring, 2015; Ralevic, 2015). Substantial evidence points to an important role of NANC transmission in the physiological regulation of the GI tract (the enteric nervous system is prominently innervated by cholinergic, adrenergic, and NANC nerve fibers), genitourinary tract, and select blood vessels. For example, nitric oxide (NO), synthesized and released from NANC nerves and endothelial cells, is an important contributor to penile erection (Burnett, 2006; Lasker et al., 2013). NO is produced in NANC neurons by neural NO synthase (nNOS) and in endothelial cells by endothelial NO synthase (eNOS). NO is considered a primary vasoactive neurotransmitter and chemical mediator, and after binding to an intracellular receptor results in the conversion of GTP to cGMP. ACh released from cholinergic nerves can bind to muscarinic receptors on endothelial cells and initiate the formation of NO. NANC neurons may also contain extensive afferent components, which are thought to contribute to the local, reflex regulation of sensory inputs.

Enteric Nervous System

Regulation of the complex physiological processes associated with gastrointestinal physiology, including secretions, motility, and nutrient absorption, are mediated to a large extent by the enteric nervous system, an intrinsic nervous system located in the wall of the gastrointestinal system. The enteric nervous system contains both motor and sensory components and is characterized by the presence of a complex intrinsic neural network that includes the myenteric plexus and the submucosal plexus. Afferent information from nerve endings in the gut wall and mucosa convey chemical, mechanical, and stretch sensory information to the intrinsic neural networks. The enteric neural networks are innervated by preganglionic PSNS nerve fibers and postganglionic SNS nerve fibers. The parasympathetic and sympathetic innervation to the enteric nervous system appears to influence the intrinsic function of this nervous system in a modulatory manner. Sensory fibers in the enteric nervous system also transmit information to sympathetic ganglia and can modulate postganglionic sympathetic nerve outflow (Evans and de Lahunta, 2013). The enteric nervous system is extensively innervated by NANC nerve fibers.

Integrated Steps in SNS and PSNS Neurotransmission

The physiology of ANS function and regulation involves numerous integrated steps, including: regulation of supraspinal and spinal autonomic neural circuits; changing the level of efferent activity in sympathetic and parasympathetic nerves that innervate peripheral organs and tissues; neurotransmitter and neuromodulator synthesis, release, and degradation; chemical transmission from nerve cell to nerve cell (e.g., ganglionic regulation); chemical transmission from nerve cells to target organ sites; receptor-mediated effects; and regulation of activity in afferent nerves. Each of these processes and functions can be manipulated by pharmacological agents, providing multiple sites for drug-mediated changes in ANS regulation and function.

Peripheral Nerve Activity and Transmission of Action Potentials

Central neural circuits are critically involved in generating the basal activity in peripheral sympathetic and parasympathetic nerves, and in altering the level of activity in these nerves in response to internal and external stimuli. The arrival of nerve impulses at axonal terminals initiates a series of physiological processes that culminate with the release of neurotransmitters and cotransmitters into the synaptic cleft. An in-depth discussion regarding fundamental physiological processes involved in the conduction of action potentials along nerve axons, including resting membrane potential, changes in membrane ionic conductances, membrane depolarization, action potential propagation, and membrane repolarization, is beyond the scope of this introductory chapter. Generally, axonal conduction is not markedly influenced by pharmacological interventions, although there are several key exceptions. For example, voltage-sensitive membrane sodium channels are blocked and axonal conduction is inhibited by local anesthetics such as lidocaine, and by tetrodotoxin (puffer fish toxin) and saxitoxin (shellfish toxin).

Neurotransmitter Synthesis, Storage, Release, and Inactivation

Cholinergic Neurons

Cholinergic nerve terminals contain several types of vesicles, including small membrane-bound vesicles that play a key role in ACh storage (Figure 6.6), and larger vesicles that contain biological substances (e.g., ATP) that are cotransmitters released simultaneously along with ACh from cholinergic nerves (Table 6.2).

The synthesis of vesicles is typically completed in neuronal cell bodies and vesicles are relocated to nerve terminals by axonal transport mechanisms. Vesicles contain numerous proteins involved in transport and trafficking processes and an extensive amount of research has been focused on understanding these cellular processes. One important functional group of proteins are termed vesicle-associated membrane proteins (VAMPs), which play a critical role in aligning ACh-containing vesicles with functional release sites on the inner neuronal cell membrane, and in initiating neurotransmitter release. Release sites on the presynaptic plasma membrane contain synaptosomal nerve-associated proteins (SNAPs), which interact with vesicle-associated membrane proteins to facilitate vesicle–plasma membrane fusion and subsequently neurotransmitter release (Figure 6.6). Botulinum toxin interferes with ACh release from cholinergic nerve terminals.

The enzyme choline acetyltransferase (ChAT) synthesizes ACh from acetyl-CoA and choline in the cytoplasm of cholinergic nerves (Figure 6.6). Neurons in the PSNS are characterized by high rates of ACh release, which is mediated by a highly efficient and rapid process of ACh synthesis. Choline is transported across the neuronal membrane from the extracellular space via a sodium-dependent membrane choline transporter (CHT; Figure 6.6), whereas acetyl-CoA is synthesized in mitochondria located in the nerve endings. Choline transport into the cell can be limited by blocking the choline transporter using a group of research drugs called hemicholiniums. Following synthesis in the cytoplasm, ACh is transported into vesicles by a vesicle-associated transporter, which can be antagonized by the research drug vesamicol. Acetylcholine storage in vesicles is characterized by the packaging of "quanta" of ACh molecules (normally 1,000 to 50,000 molecules in each vesicle).

Release of ACh neurotransmitter from vesicles in cholinergic nerves is dependent on the arrival of action potentials at neuronal membrane terminals which activate voltage-gated calcium channels allowing for inward movement of Ca^{2+} into the nerve terminal (Figure 6.6). Calcium initiates processes that are essential for the vesicle membrane fusion with the neuronal membrane, leading to the exocytotic discharge of neurotransmitter into the synaptic cleft. Following release of ACh from cholinergic nerve terminals, ACh molecules may bind to and activate nicotinic (primarily ganglionic sites in the ANS) and muscarinic (primarily cells and tissues at target sites innervated by postganglionic nerves) receptors. Atropine and related alkaloids are muscarinic receptor antagonists whereas chlorisondamine blocks N_N receptors.

Nicotinic and muscarinic receptors are also present at presynaptic sites. Following release of ACh from cholinergic nerve terminals, this neurotransmitter can

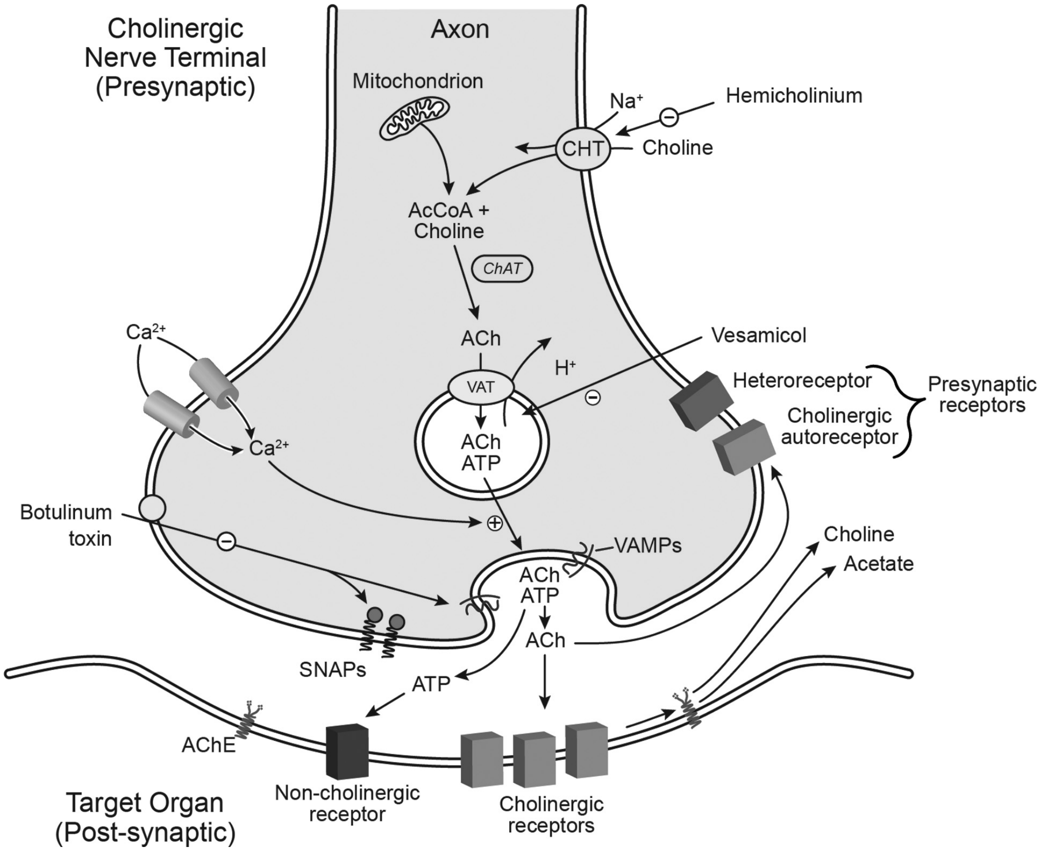

Figure 6.6 Schematic diagram depicting physiological processes at the site of a postganglionic parasympathetic nervous system neuron innervating a target tissue. Processes are described in the text and include: neurotransmitter synthesis, storage, and release; chemical transmission from nerve cells to target organ cells and tissues; neurotransmitter activation of presynaptic receptors; and termination of neurotransmitter action.

bind to and activate presynaptic cholinergic autoreceptors, primarily nicotinic receptors on preganglionic neurons and muscarinic receptors on postganglionic neurons, which in turn attenuate the release of ACh. This physiological process provides a pathway via which the release of ACh from a specific cholinergic neuron is regulated at a local level, an autoregulatory process. Cholinergic receptors also function as heteroreceptors, that is ACh released from cholinergic nerve terminals can bind to nicotinic or muscarinic receptors located on the presynaptic terminals of adjacent neurons, such as sympathetic nerve terminals, and inhibit the release of neurotransmitters from these neurons, such as NE from postganglionic sympathetic neurons.

As stated previously, cotransmitter molecules or biological substances are released along with ACh at target sites innervated by postganglionic parasympathetic neurons. Physiological functions of PSNS cotransmitters include modulating the presynaptic release of ACh, producing synergistic actions with ACh, and activating different postjunctional cells. In general, PSNS cotransmission at synaptic sites provides increased pharmacological and physiological finesse in the regulation of target tissue responses.

The binding of ACh to cholinergic receptors is transient and ACh located in the synaptic space is inactivated by acetylcholinesterase (AChE) (Figure 6.6), an enzyme that rapidly hydrolyzes ACh into choline and acetate. AChE is located in close proximity to the synaptic cleft at most cholinergic synapses, including postganglionic parasympathetic neuroeffector sites, and is present in autonomic ganglia, cholinergic nerves, and at neuromuscular junctions. The distribution of ACh released from cholinergic neurons is localized because AChE is efficient at terminating the action of ACh at synaptic sites. The amount of ACh available at synaptic sites, and subsequently its functional activity, can be enhanced by drugs and chemicals that block AChE (e.g., acetylcholinesterase agents). AChE is found in other body tissues, including red blood cells.

Adrenergic Neurons

Many animal species synthesize and secrete three endogenous catecholamines: NE, EPI, and dopamine. Biochemical steps in the synthesis of catecholamines are shown in Figure 6.7. Catecholamine synthesis is initiated by the conversion of phenylalanine to tyrosine by the enzyme phenylalanine hydroxylase. The enzyme tyrosine

D_2 (DA_2), D_3, D_4 D_5	CNS; smooth muscle; presynaptic nerve terminals	G_i/G_o	↓ Intracellular cAMP; ↑ K^+ currents

CNS, central nervous system; SNS, sympathetic nervous system; PNS, parasympathetic nervous system; PLC, phospholipase C; PLA, phospholipase A; IP_3, inositol-1, 4, 5-triphosphate; DAG, diacylglycerol; cAMP, cyclic AMP.

hydroxylase converts tyrosine to dihydroxyphenylalanine (dopa), and this enzymatic step is considered the rate-limiting step in catecholamine synthesis. Dopa is decarboxylated by the enzyme L–aromatic amino acid decarboxylase (dopa decarboxylase) to form dihydroxyphenylethylamine (dopamine), which is transported into and stored in granules. In some neurons and neuronal systems, including select peripheral postganglionic sympathetic neurons and neurons in several CNS sites (e.g., mammalian extrapyramidal system), catecholamine synthesis terminates with dopamine. These neurons release dopamine as the primary neurotransmitter and are identified as dopaminergic neurons. Dopamine–β-hydroxylase mediates the conversion of dopamine to NE, and this conversion is the terminal enzymatic step in catecholamine synthesis in postganglionic SNS neurons and in some CNS neurons. The chromaffin cells of the adrenal medulla synthesize and release EPI and NE. In some adrenal medullary cells the terminal step in the biosynthesis of catecholamines involves conversion of dopamine to NE, whereas in other cells NE is released from the granules and is converted to EPI within the cytoplasm by phenylethanolamine *N*-methyltransferase, and subsequently re-enters the chromaffin granules prior to release from the adrenal medulla. EPI (~80%; NE, ~20%) is the primary catecholamine released from the adrenal medulla. The enzymatic conversion of NE to EPI also occurs in select CNS sites. The level of catecholamines contained in the cytoplasm is closely regulated by two physiological

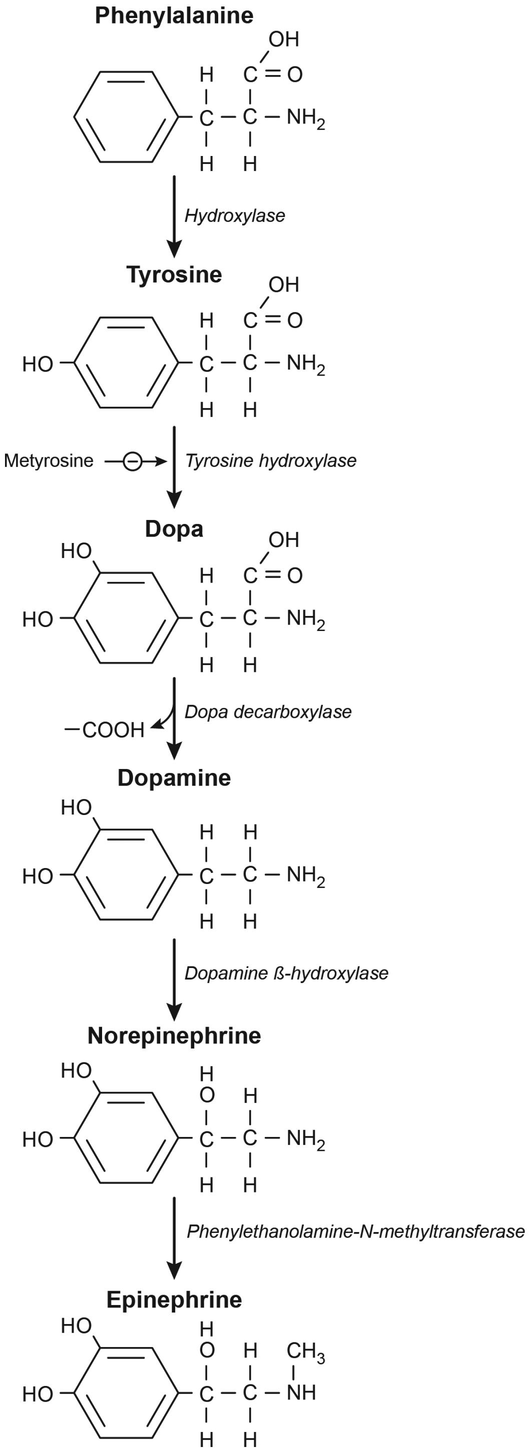

Figure 6.7 Biosynthesis of catecholamines. The rate-limiting step is the conversion of tyrosine to dopa by the enzyme tyrosine hydroxylase. Generally, postganglionic sympathetic nervous system neurons do not contain the enzyme, phenylethanolamine-*N*-methyltransferase (PMNT), therefore, the enzymatic conversion of dopamine to norepinephrine is the final step in catecholamine biosynthesis in these neurons. The enzymatic conversion of norepinephrine to epinephrine by PMNT occurs primarily in the adrenal medulla and in specific central nervous system sites.

processes: inactivation by the neuronal mitochondrial enzyme monoamine oxidase (MAO); and transportation of cytoplasmic NE into granules by the vesicular monoamine transporter. NE, EPI, dopamine, and serotonin are all transported by monoamine transporters and reserpine inhibits this process and leads to depletion of the amount of stored neurotransmitter.

The exocytic process of releasing neurotransmitters and cotransmitters from granules contained in adrenergic nerve endings is initiated by arrival of an action potential at the nerve terminal (Figure 6.8), is calcium dependent, and is similar in many aspects to the release of ACh from cholinergic nerves. Although NE is the primary neurotransmitter released from postganglionic sympathetic nerves, there are several cotransmitters that can be simultaneously released, including ATP, NPY, and other peptide molecules. These additional neurotransmitters or neuromodulators may be costored with NE or may be stored in separate vesicles. The functions of cotransmitters in synaptic neurotransmission are varied and multifactorial and may include direct postsynaptic receptor effects, modulation of receptor effects of other adrenergic neurotransmitters or cotransmitters, and alteration of the presynaptic release of neurotransmitters or neuromodulators.

Following release from postganglionic sympathetic nerve terminals, NE molecules can bind to and activate adrenergic receptors located on postsynaptic cells and tissues, as well as activate presynaptic adrenergic receptors located on the postganglionic nerve terminal from which the catecholamine was released (Figure 6.8). α_2-adrenergic receptors (with a specific emphasis on the α_{2A}-adrenergic receptor subtype) are the primary presynaptic receptors that, when activated, mediate an autoregulatory response to inhibit transmitter release at selected postganglionic SNS nerve terminals. The release of NE from postganglionic SNS neurons can also be reduced by several of the cotransmitters that are released simultaneously with NE. Conversely, the release of NE from postganglionic SNS neurons can be augmented by activation of presynaptic β_{2}-adrenergic receptors. Adrenergic receptors located on the presynaptic terminals of adjacent neurons, such as nearby parasympathetic nerve terminals, can function as heteroreceptors. For example, NE released from postganglionic sympathetic nerve terminals can bind to adrenergic receptors located on parasympathetic nerve terminals and inhibit ACh release. Similarly, the activation of heteroreceptors located on sympathetic nerve terminals, such as the binding of ACh to muscarinic receptors expressed on postganglionic SNS neurons, can inhibit the release of catecholamines from sympathetic nerve terminals.

As a physiological strategy to reduce overstimulation of adrenergic receptors secondary to neuronal release

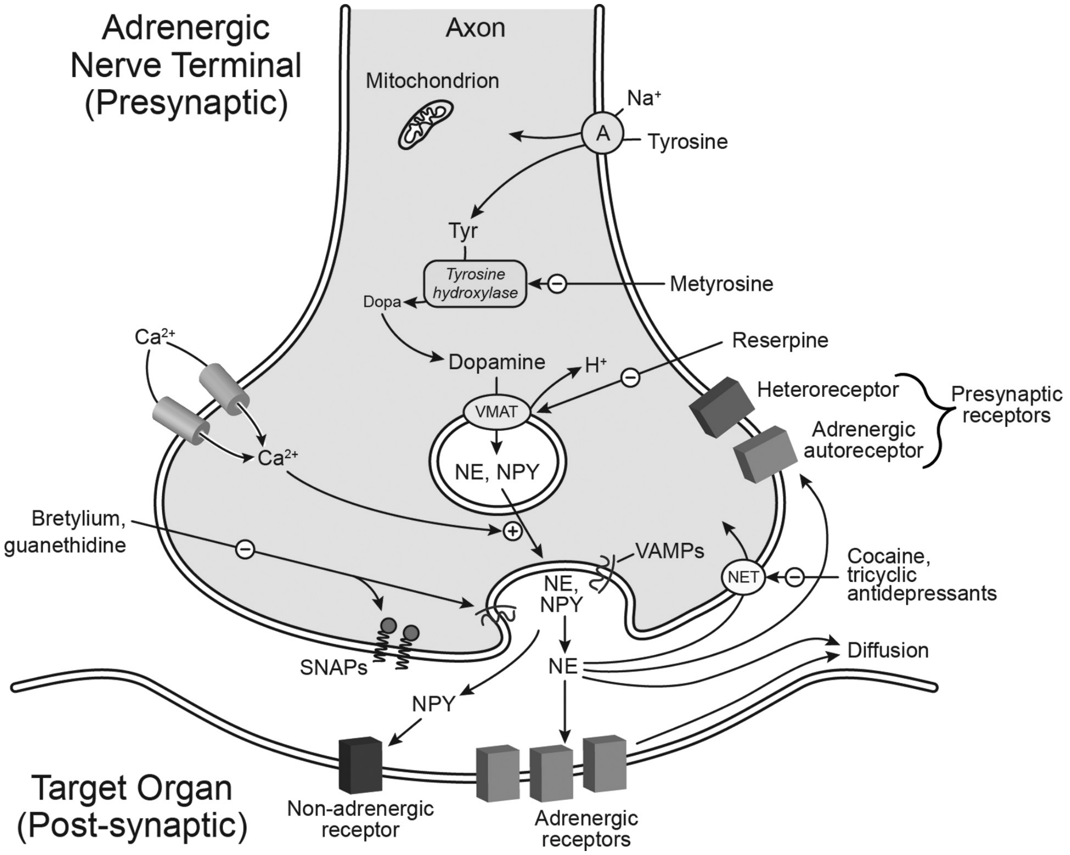

Figure 6.8 Schematic diagram depicting physiological processes at the site of a postganglionic sympathetic nervous system neuron innervating a target tissue. Processes are described in the text and include: neurotransmitter synthesis, storage, and release; chemical transmission from nerve cells to target organ cells and tissues; neuronal reuptake of neurotransmitter; neurotransmitter activation of presynaptic receptors; and termination of neurotransmitter action.

of NE, the amount of NE contained in the synapse is tightly regulated. Elimination of synaptic NE and/or termination of NE synaptic activity occurs via three physiological processes. First, NE can be metabolized by the enzyme catechol-*O*-methyltransferase (COMT) that is located at postsynaptic cell membrane-associated neuroeffector sites. Second, NE (as well as other similar molecules) can be transported back into postganglionic sympathetic nerve terminals (or nearby glial cells) by an active norepinephrine transporter (NET, also termed uptake 1 or reuptake 1) reuptake system that is present in axonal membranes (Figure 6.8). In a similar process, synaptic dopamine can be taken back into dopaminergic cells by a membrane dopamine transporter. NE that has been transported back into the neuron may be recycled and placed in granules or undergo metabolic breakdown via mitochondrial MAO. Inhibition of NET, mediated by cocaine and tricyclic antidepressant drugs, results in an increase in the level of NE in the synaptic cleft and enhanced receptor-mediated effects. Third, NE can diffuse away from the synaptic cleft and be metabolized in the plasma or liver, or excreted in the urine. Hepatic COMT is critically involved in the metabolism of endogenous circulating and administered catecholamines. It is generally considered that the reuptake of synaptic NE into adrenergic nerve terminals and the diffusion of NE from synaptic areas and subsequent enzymatic degradation are the primary processes involved in terminating NE activity. Metabolism of endogenous catecholamines by MAO and COMT involves numerous pathways (Figure 6.9).

Autonomic Receptors

Multiple experimental interventions (including structure–activity analyses, binding of isotope-labeled ligands, pharmacokinetic and pharmacodynamic analyses of specific autonomic agonists and antagonists, and molecular biological and proteomic analyses) have been used to identify and characterize receptors involved in ANS regulation. These include nicotinic and muscarinic cholinergic receptors, as well as alpha, beta, and dopaminergic adrenergic receptors (Wilson-Pauwels et al., 1997; Yamada and Ito, 2001; Abrams and Andersson, 2007; Yoshimura et al., 2008; Andersson,

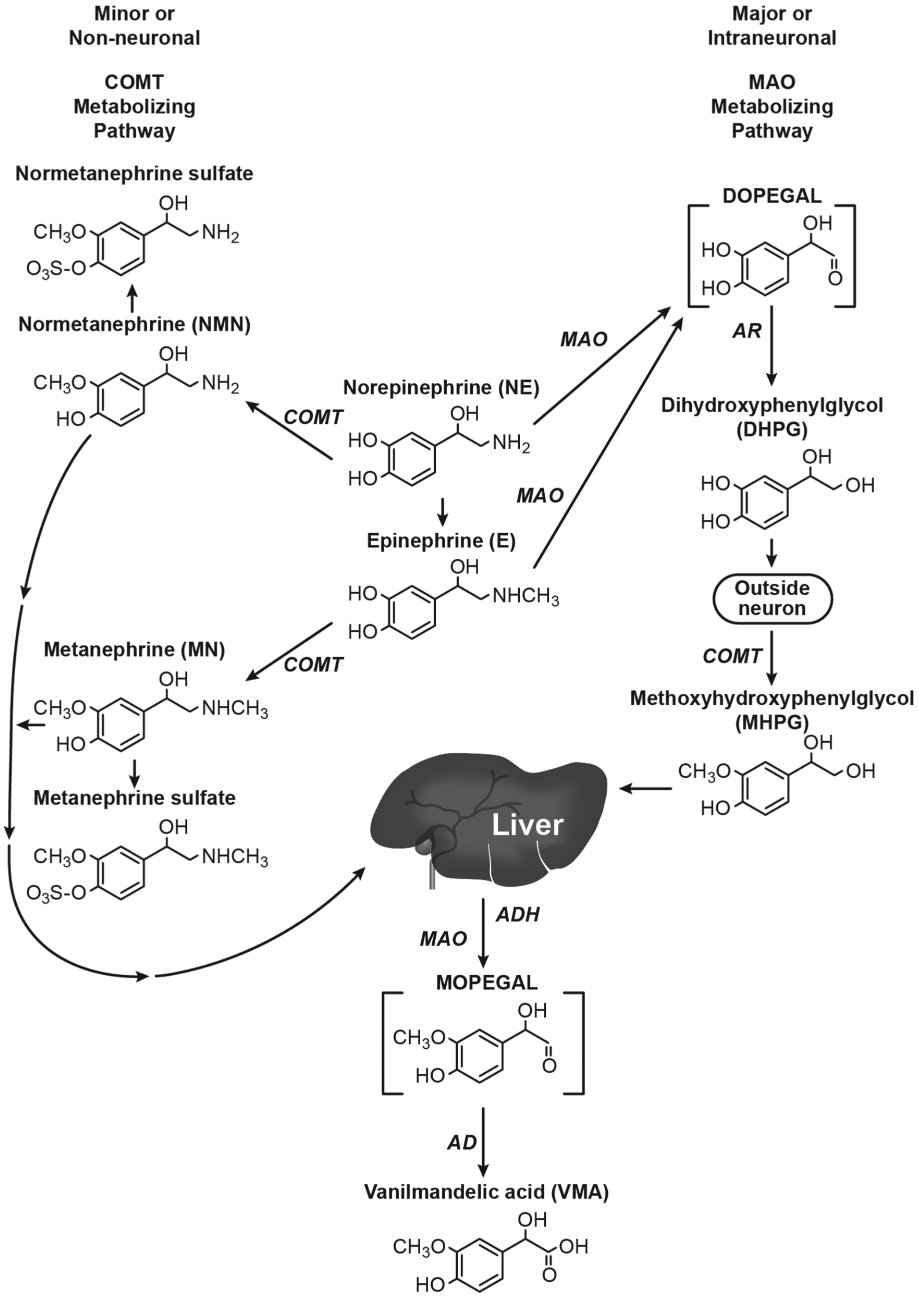

Figure 6.9 Flow diagram illustrating the metabolism of norepinephrine and epinephrine by catechol-*O*-methyltransferase (COMT) and monoamine oxidase (MAO). Source: Adapted from Oeltmann 2004. Reproduced with permission of Elsevier.

2011; Cazzola et al., 2012; Lei, 2014; Herring, 2015). Specific receptor information is summarized in Table 6.2 (receptors/sites/G proteins/secondary messengers) and described in subsequent sections.

Cholinergic Receptors

As stated previously, ACh is the primary agonist at two types of cholinergic receptors (the term cholinoceptor is often used interchangeably): nicotinic and muscarinic. These receptors were named according to the alkaloids (nicotine and muscarine) that were identified to be agonists at the respective receptors.

Nicotinic Receptors: Anatomical Location, Receptor Subtypes, and Signal Transduction

Peripherally located autonomic N_N receptors are present on postganglionic neurons in autonomic ganglia (intramural, prevertebral, and paravertebral) and mediate neurotransmission from preganglionic to postganglionic neurons in both arms of the ANS. N_N receptors are also present on adrenal medullary chromaffin cells and mediate neurotransmission from preganglionic SNS neurons to adrenal medullary chromaffin cells. Nicotinic receptors are widely distributed in the CNS and are present in nonneuronal tissues. Nicotinic muscle (N_M) receptors are critically involved in mediating signal transmission at the neuromuscular junction and are an essential component of the somatic nervous system (SoNS) (Figure 6.5).

Nicotinic receptors are ligand-gated ion channels and contain five homologous subunits organized around a central pore (Stokes et al., 2015). Activation of these receptors initiates a rapid increase in cellular permeability to selective cations (Na^+ and Ca^{2+}); cell membrane depolarization; and excitation of postganglionic ANS neurons, adrenal medullary chromaffin cells, or skeletal muscle fibers (Stokes et al., 2015).

As previously discussed, in addition to their anatomical location at postsynaptic sites on effector cells, nicotinic receptors are located at presynaptic sites. Activation of these receptors influences the release of neurotransmitters from neurons at peripheral sites and in the CNS.

Muscarinic Receptors: Anatomical Location, Receptor Subtypes, and Signal Transduction

Muscarinic receptors are located predominately at postsynaptic target sites innervated by postganglionic parasympathetic nerves such as the heart, glands, urinary bladder, and gastrointestinal tract, thereby establishing a pivotal role for these receptors in the functionality of the PSNS. Five subtypes of muscarinic receptors have been identified, each associated with a different gene, and many of the physiological functions associated with PSNS activation are mediated by muscarinic$_2$ (M_2) and muscarinic$_4$ (M_4) receptors. Muscarinic receptor subtypes are located in distinct peripheral anatomic locations (Table 6.2) and demonstrate differential specificities to various agonists and antagonists.

Muscarinic receptors are G protein-coupled receptors (GPCRs), and activation of these receptors may elicit an excitatory or inhibitory response (Calebiro et al., 2010; Jalink and Moolenaar, 2010; Ambrosio et al., 2011; Vischer et al., 2011; Latek et al., 2012; Duc et al., 2015). A fundamental mechanism mediating the capability of the PSNS to produce an assortment of physiological response profiles arises from the fact that specific muscarinic receptors couple primarily to specific G proteins. Muscarinic receptor subtypes M_1, M_3, and M_5 couple through $G_{q/11}$, whereas M_2 and M_4 receptors couple to G_i and $G_{0.}$ Specificity in the intracellular response profiles following activation of specific muscarinic receptors are the result of G protein-mediated effects on the generation of second messengers and on the activity of ion channels (Table 6.2).

As described previously, and in addition to their anatomical location at postsynaptic sites on effector cells innervated by postganglionic PSNS neurons, muscarinic receptors are located at presynaptic and perisynaptic sites and activation of these receptors influences the release of neurotransmitters from neurons at peripheral sites and in the CNS.

Adrenergic Receptors

The endogenous catecholamines NE and EPI are agonists at α- and β-adrenergic receptors (also termed adrenoceptors), whereas dopamine, the metabolic precursor of NE, is a primary agonist at dopaminergic receptors.

Adrenergic Receptors: Anatomical Location, Receptor Subtypes, and Signal Transduction

The concept of distinct adrenergic receptors (α and β) as determined by their relative responsiveness to specific receptor agonists was first proposed in a classic paper authored by Ahlquist (1948). There are two types of α-adrenergic receptors; α_1 and α_2. Each type contains specific receptor subtypes, designated as α_{1A}, α_{1B}, and α_{1D}; and α_{2A}, α_{2B}, and α_{2C}. There are three primary types of β-adrenergic receptors, β_1, $\beta_{2,}$ and $\beta_{3,}$ and two primary types of dopaminergic receptors, dopamine$_1$, D_1, and dopamine$_2$, D_2.

α- and β-adrenergic receptors are expressed predominately at target sites innervated by postganglionic sympathetic nerves, and their placement is characterized by a substantial degree of anatomical specificity (adrenergic types and designated tissue locations are summarized in Table 6.2). β-adrenergic receptors are expressed in the heart (primarily β_1), urinary bladder (primarily β_2 and β_3), liver (primarily β_2), kidney (primarily β_1); and in bronchial (primarily β_2), uterine (primarily β_2 and β_3), and vascular (primarily β_2) smooth muscle. It is often considered that vascular smooth muscle β_2-adrenergic receptors are not innervated by postganglionic sympathetic nerve fibers and circulating catecholamines released from the adrenal medulla are the primary endogenous agonists for these receptors. β-adrenergic receptors regulate many physiological functions including: heart rate and cardiac contractility; renin release; smooth muscle relaxation; and numerous metabolic events in adipose, skeletal muscle, and hepatic cells (see Table 6.1). α_1-adrenergic receptors are expressed in numerous tissues and organs including vascular smooth muscle, radial muscle of the iris, and smooth muscle in the genitourinary system. It is generally considered that α_1-adrenergic receptors are in close proximity to postganglionic sympathetic nerve endings, and NE released from these neurons is a primary endogenous agonist for these receptors. α_2-adrenergic receptors are expressed in a variety of cells and tissues including: vascular smooth muscle; thromobocytes; endothelial cells that synthesize and release nitric oxide; CNS sites; and on the terminals of postganglionic sympathetic nerve fibers.

Adrenergic receptors (α and β) are G protein-coupled receptors that link to G proteins (Calebiro et al., 2010; Jalink and Moolenaar, 2010; Ambrosio et al., 2011; Vischer et al., 2011; Latek et al., 2012; Duc et al., 2015).

A fundamental mechanism underpinning the capability of the ANS to produce various types of physiological response profiles arises from the fact that specific adrenergic receptors couple primarily to specific G proteins. For example, α_1 receptors couple to G_q, α_2 receptors couple to G_i, and β-adrenergic receptors couple to G_s. Specificity in the intracellular response profiles following activation of specific adrenergic receptors are the result of G protein-mediated effects on the generation of second messengers and on the activity of ion channels (Table 6.2).

As stated above, α_2-adrenergic receptors are expressed on the terminals of sympathetic nerve fibers, and NE released from postganglionic sympathetic neurons may interact with α_2-adrenergic receptors located at presynaptic sites to reduce NE release. The α_{2A}-adrenergic receptor subtype is considered to play an important role in this autoregulatory function. α-adrenergic receptors, especially α_2 receptors, can also be classified as heteroreceptors. For example, NE released from postganglionic sympathetic nerve fibers can modulate ACh release by activating α_2-adrenergic receptors that are expressed on parasympathetic neurons.

Dopamine mediates numerous physiological effects in the CNS and at peripheral targets, including the vasculature in many visceral organs. The D_1 receptor is generally associated with stimulation of adenylyl cyclase and increased cAMP, which may mediate the vasodilatory effects of dopamine in the renal and splanchnic circulations. On the other hand, activation of D_2 receptors has been shown to inhibit adenylyl cyclase activity, open potassium channels, and decrease calcium influx. D_2 receptors are expressed on the terminals of postganglionic sympathetic nerve fibers, and activation of these presynaptic dopaminergic receptors can produce the inhibition of NE from these nerve terminals.

Adrenergic Receptor Agonists and Antagonists

Rose M. McMurphy, Elizabeth G. Davis, Amy J. Rankin, Daniel A. Frese, Barbara J. Lutjemeier, and Michael J. Kenney

Classification of Adrenergic Agonists

The sympathetic nervous system (SNS) influences the regulation of most organ systems and plays a critical role in regulating physiological homeostasis under basal conditions and in response to acute and sustained stressors. Changes in physiological function are initiated and sustained by altering the level of efferent sympathetic nerve outflow, which in turn affects the release of norepinephrine (NE) from postganglionic nerve terminals. Sympathetic nerve activity mediates NE release from nerve terminals, and the released NE binds to and activates adrenergic receptors located on postsynaptic effector tissues and at presynaptic sites. In a similar fashion, central activation of sympathetic nerve activity directed to the adrenal medulla initiates the release of epinephrine (EPI) and some NE from this gland, which circulates in the blood and binds to and activates adrenergic receptors in target tissues.

Drugs that mimic the pharmacological and physiological actions of the endogenous catecholamines are classified as sympathomimetic drugs, that is their effects are mediated by activation of adrenergic receptors located on effector cells and tissues. One framework for classifying the functionality of adrenergic receptor agonists is centered on their general pharmacological mechanism of action (Figure 7.1). Three classifications are often considered. The first group, which includes the endogenous catecholamines (e.g., NE and EPI) and many sympathomimetic drugs (e.g., phenylephrine, dobutamine), are classified as direct agonists. These neurotransmitters and drugs bind directly to and activate adrenergic receptors (Figure 7.1). Many adrenergic agonists used in clinical medicine are direct adrenergic receptor agonists. A second group is classified as indirect-acting agonists because they mediate physiological responses via a pharmacological mechanism of action that involves increasing the synaptic levels of endogenous catecholamines, thereby enhancing the availability of endogenous catecholamines to bind to adrenergic receptors. This effect can be achieved by three different mechanisms of action: (i) reducing the metabolic breakdown of catecholamines by pharmacologically blocking or antagonizing endogenous enzymes involved in the metabolism of NE and EPI (e.g., monoamine oxidase inhibitors); (ii) inhibiting the physiological processes involved in the reuptake of NE from the synaptic space into postganglionic sympathetic nerve terminals (e.g., cocaine and tricyclic antidepressants); and (iii) enhancing the release of catecholamines from postganglionic sympathetic nerve terminals (e.g., tyramine). Some drugs (e.g., ephedrine) demonstrate the capability to directly activate adrenergic receptors as well as augment the release of NE from adrenergic nerve terminals, and these drugs are classified as mixed-acting adrenergic agonists (Figure 7.1). In a conceptual context, the physiological responses produced by direct, indirect, and mixed-acting agonists are similar to responses produced by activating central sympathetic neural circuits, increasing the level of efferent sympathetic nerve outflow, and inducing the release of NE from postganglionic sympathetic nerves.

Sympathomimetic Amines and Structure–Activity Relationships

The capacity of sympathomimetic drugs to produce physiological responses consistent with functional patterns produced by SNS activation depends on the similarity of the chemical structure of sympathomimetic drugs to that of NE and EPI. The parent compound of sympathomimetic amines is β-phenylethylamine, which consists of a benzene ring and an ethylamine side chain. Chemical substitutions can be made on the aromatic ring, on the α and β carbons atoms, and on the terminal amino group to produce compounds with sympathomimetic activity.

The endogenous adrenergic receptor agonists EPI, NE, and dopamine, as well as the synthetic sympathomimetic isoproterenol, contain a hydroxyl group on the 3 and 4 positions of the benzene ring. The 3,4-dihydroxybenzene structure is also known as catechol; therefore sympathomimetic amines that contain this nucleus are known as

catecholamines. For the most part, the catechol nucleus is required for maximum α- and β-adrenergic receptor potencies, and modifications in phenylethylamine mediate changes in the affinity of drugs for specific adrenergic receptors, and affect the intrinsic ability to activate these receptors. Removal of one or both hydroxyl groups from the aromatic ring reduces β-adrenergic receptor activity. For example, phenylephrine, a specific α_1-adrenergic receptor agonist, is identical in structure to EPI, a mixed α-β-adrenergic receptor agonist, except for the lack of one hydroxyl group on the ring (Table 7.1). Substitution on the β-carbon atom of the side chain produces a compound with reduced central nervous system (CNS) effects, whereas substitution on the α-carbon atom produces a drug that is generally more resistant to oxidation by monoamine oxidase (MAO). The α- and β-agonistic properties of various drugs are affected by alkyl substitutions on the amino group. Collectively, this information supports the idea that pharmacological profiles of specific agonists differ depending upon chemical structure. The chemical structures and related pharmacological characteristics of the endogenous catecholamines and several adrenergic drugs are summarized in Table 7.1.

Activation of Adrenergic Receptors and Cell Signaling

Physiological responses produced by catecholamines and sympathomimetic drugs are initiated by the binding of agonists to adrenergic receptors located on the cell surface (Wilson-Pauwels et al., 1997; Yamada and Ito, 2001; Cazzola et al., 2012; Lei, 2014; Herring, 2015). Adrenergic receptors are G protein-coupled receptors

Table 7.1 Chemical structures of catecholamines and selected sympathomimetic drugs

Drug		β CH	α CH	NH
β-phenylethylamine	…	H	H	H
β-phenylethanolamine	…	OH	H	H
Catecholamines				
Dopamine	3-OH, 4-OH	H	H	H
Norepinephrine	3-OH, 4-OH	OH	H	H
Epinephrine	3-OH, 4-OH	OH	H	CH_3
Isoproterenol	3-OH, 4-OH	OH	H	$CH(CH_3)_2$
Noncatecholamines

(GPCRs) (Calebiro et al., 2010; Jalink and Moolenaar, 2010; Ambrosio et al., 2011; Vischer et al., 2011; Latek et al., 2012; Duc et al., 2015). G proteins are classified by their specific subunits, and select G proteins regulate specific effector proteins and interact with select molecular pathways. Membrane and intracellular processes associated with GPCRs have been previously introduced in Chapter 6.

The β-adrenergic receptor family is composed of three different subtypes (β_1, β_2, and β_3). Activation of β receptors, regardless of subtype, results in stimulation of adenylyl cyclase and increased cAMP, mediated via the stimulatory coupling protein G_s (Table 7.2). β-adrenergic receptors (β_1, β_2, and β_3) are expressed in numerous tissues and organs (Table 7.3), although for a given tissue a specific receptor subtype may be more prominently

Table 7.3 Anatomical distribution of adrenergic receptor subtypes and general physiological effectors produced in response to activation of specific adrenergic receptors

Receptor	Tissue	Response
α_1	Most vascular smooth muscle (innervated)	Contraction
	Pupillary dilator muscle	Contraction (dilates pupil)
	Splenic capsule	Contraction
	Urethral smooth muscle	Contraction
α_2	Postsynaptic CNS neurons	Numerous sites
	Platelets	Aggregation
	Adrenergic and cholinergic nerve terminals	Inhibits transmitter release
	Selected vascular smooth muscle	Contraction
β_1	Heart, juxtaglomerular cells	Increases force and rate of contraction; increases renin release
β_2	Respiratory, uterine, and vascular smooth muscle	Smooth muscle relaxation
	Liver	Gluconeogenesis
β_3	Fat cells	Activates lipolysis
D_1	Vascular smooth muscle	Dilates select blood vessels
D_2	Autonomic nerve terminals	Modulates neurotransmitter release from nerve terminals

expressed when compared with other receptor subtypes, thereby providing the tissue or organ with a relatively specific β-adrenergic subtype signature. For example, cardiac functions, such as increased heart rate and enhanced cardiac contractility, are medicated to a prominent extent by activation of cardiac β_1-receptors, whereas relaxation of bronchial smooth muscle involves activation of bronchial smooth muscle β_2-adrenergic receptors.

β-adrenergic receptors are expressed in smooth muscle at multiple anatomical sites, including: pulmonary airways (β_2 receptors), vascular smooth muscle (β_2 receptors), and the detrusor muscle of the bladder (β_2 and β_3 receptors). Activation of β receptors in these tissues mediates smooth muscle relaxation contributing to bronchodilation, vasodilation of vascular smooth muscle with accompanying reduced vascular resistance, and relaxation of the bladder body. Smooth muscle relaxation secondary to activation of β-adrenergic receptors may be mediated via processes that include the phosphorylation of myosin light-chain kinase to an inactive form. In many species the innervation of vascular smooth muscle β_2-adrenergic receptors by postganglionic sympathetic nerves is rather sparse, suggesting that the primary activation of these receptors is mediated by circulating EPI released from the adrenal medulla. β-adrenergic receptors (generally thought to be β_2 receptors) are also located at presynaptic sites on postganglionic nerve terminals and, in general, activation of presynaptic β_2-adrenergic receptors facilitates the release of NE.

The α_1-receptor family includes three subgroups: $\alpha_{1A,}$ $\alpha_{1B,}$ and $\alpha_{1D.}$ Binding of an agonist to α_1-adrenergic receptors, regardless of subtype, activates phospholipase C, mediated via activation of a G_q coupling protein, which leads in many cases to the formation of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol, and multiple functional effects including the release of intracellular Ca^{2+} stores (Table 7.2). Although the distribution (Table 7.3) and activation of different α_1-adrenergic receptor subtypes provides the substrate for a diverse profile of physiological responses, the functional signature of α_1-adrenergic receptor activation is smooth muscle contraction, including contraction of vascular smooth muscle, the radial muscle of the iris (iris dilator muscle), and smooth muscle in the genitourinary system. Generally, α_1-adrenergic receptors located in vascular smooth muscle are in close proximity to postganglionic sympathetic nerve endings, therefore they are considered innervated vascular receptors.

The $\alpha_{2\text{-}}$receptor family includes three subgroups: $\alpha_{2A,}$ $\alpha_{2B,}$ and $\alpha_{2C.}$ In many targets the physiological responses to activation of α_2 receptors involves the coupling of these receptors to the inhibitory regulatory protein G_i (Table 7.2), resulting in inhibition of adenylyl cyclase activity and reduced intracellular cAMP levels. It is known that other signaling pathways, separate from the inhibition of adenylyl cyclase, are involved in mediating intracellular processes to $\alpha_{2\text{-}}$receptor activation. α_2-adrenergic receptors are expressed in a variety of cells and tissues (Table 7.3), including vascular smooth muscle, thromobocytes, endothelial cells, and in the CNS. α_2-adrenergic receptors are located on the terminals of postganglionic sympathetic nerve fibers, and activation of these presynaptic adrenergic receptors by endogenous catecholamines and other sympathomimetics reduces NE release from nerve terminals.

By binding to and activating specific receptors at both central and peripheral sites, the endogenous catecholamine dopamine produces numerous physiological effects. Activation of the dopamine$_1$ (D_1) receptor is generally associated with increased cAMP, whereas activation of dopamine$_2$ (D_2) receptors can inhibit adenylyl cyclase activity.

Adrenergic Receptor Selectivity and Tissue Distribution

Overview

The breadth and diversity of (i) adrenergic receptor types and subtypes, (ii) G-proteins, and (iii) second messenger systems provides the cellular and molecular substrate for mediating the myriad number of physiological responses produced by activation of the SNS. In addition, many adrenergic receptor agonists demonstrate a level of selectivity for specific adrenergic receptors. An individual endogenous catecholamine or sympathomimetic drug may exhibit a higher affinity or selectivity for one or more subtypes of adrenergic receptors. Receptor selectivity provides an important framework for understanding target organ effects of endogenous catecholamines and sympathomimetic drugs. However, receptor selectivity for a given agonist is generally not absolute; that is, at higher concentrations a given drug or catecholamine may interact with and activate other subtypes or classes of adrenergic receptors, providing the functional basis for considering a spectrum of relative receptor affinities for most adrenergic agonists. Examples of relative receptor affinities for endogenous catecholamines of select adrenergic drugs are listed in Table 7.4. EPI is an agonist at α_1-, α_2-, β_1-, and β_2-adrenergic receptors, whereas NE is an agonist at α_1-, α_2-, and β_1-adrenergic receptors, with less potent effects on β_2-adrenergic receptors. Isoproterenol is a β_1- and β_2-adrenergic receptor agonist whereas phenylephrine is a selective α_1-adrenergic receptor agonist (Table 7.4).

The anatomical location of specific adrenergic receptor types and subtypes plays a key role in mediating the functional/physiological responses produced by a given

Table 7.4 Classification of adrenergic receptor agonists and their relative selectivity for specific adrenergic receptors

Agonists	Receptor selectivity
Alpha agonists

drug or catecholamine. Pharmacological interactions between specific agonists and adrenergic receptors, as well as the profile of physiological responses produced by agonist–receptor interactions, are diverse and dynamic and are influenced by a number of factors, including: the tissue distribution of adrenergic receptors; the number of adrenergic receptors expressed at specific sites; interactions between the sympathetic and parasympathetic nervous systems at target sites; specific pathophysiological and disease states; the background level of sympathetic nerve activity; and levels of endogenous catecholamines and/or sympathomimetic drugs. Regarding the latter, prolonged exposure of adrenergic receptors to specific agonists reduces the responsiveness of these receptors to agonist activation, producing a progressive attenuation in the tissue's capacity to facilitate physiological responses. This physiological phenomenon is known as desensitization of adrenergic receptors. Multiple cellular and molecular mechanisms likely play a role in mediating adrenergic receptor desensitization, including changes in the number of adrenergic receptors and in intracellular signaling mechanisms.

Cardiovascular Responses to Adrenergic Receptor Agonists: Effects of Adrenergic Receptor Selectivity and Distribution

The pivotal contributions of adrenergic receptor selectivity and tissue distribution in mediating physiological responses to sympathomimetic drugs can be highlighted by comparing the effects of specific endogenous catecholamines and sympathomimetic drugs on various physiological regulatory systems, including cardiovascular regulation. In this section the cardiovascular effects (blood pressure, heart rate, myocardial contractility, cardiac output) produced by the administration of phenylephrine (selective α_1-adrenergic receptor agonist), NE and EPI (endogenous catecholamines), and isoproterenol (β_1- and β_2-adrenergic receptor agonist) are compared, with an emphasis on integrating and explaining how differences in their affinity or selectivity for specific α- and β-adrenergic receptors, and the primary anatomical location of specific adrenergic receptors, contribute to the

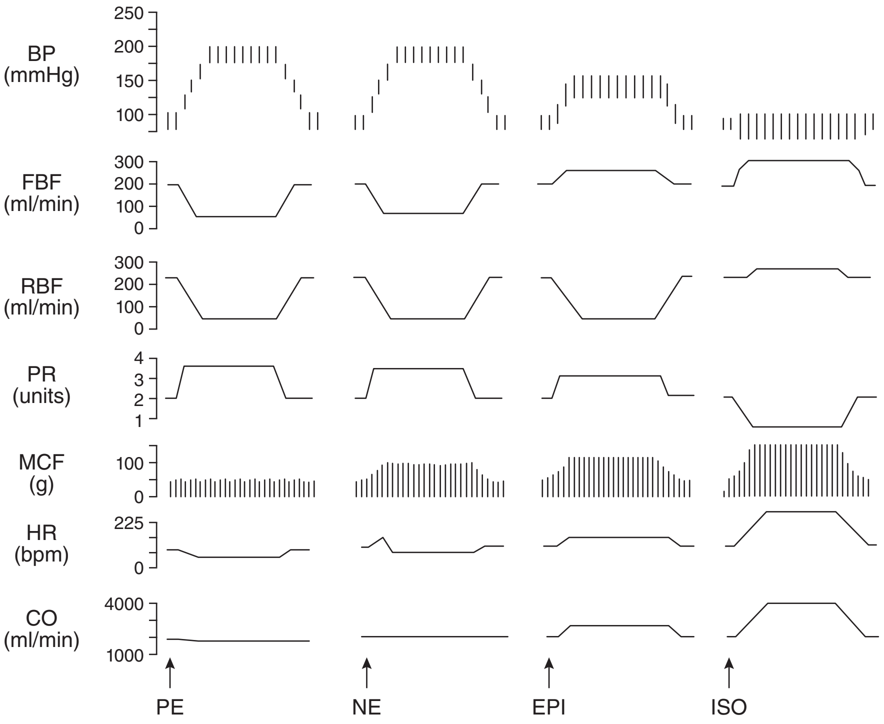

Figure 7.2 Schematic showing cardiovascular effects in response to the intravenous administration of four adrenergic agonists (phenylephrine (PE), norepinephrine (NE), epinephrine (EPI), and isoproterenol (ISO)) characterized by different relative receptor affinity profiles. Schematic representations of approximate equivalent doses of these endogenous catecholamines and sympathomimetic amines on blood pressure (BP), femoral blood flow (FBF), renal blood flow (RBF), peripheral vascular resistance (PR), myocardial contractile force (MCF), heart rate (HR), and cardiac output (CO). See text for explanation of the cardiovascular responses.

Table 7.5 Selected adrenergic receptors that play a role in cardiovascular regulation, their primary distributions in the vasculature and heart, general cardiovascular responses produced by their activation, and the selectivity of agonists (EPI, NE, ISO, and PE) for the specific adrenergic receptors

Receptor	Tissue	Physiological response	Agonist selectivity
α	Blood vessels	Vasoconstriction	PE; EPI > NE >>> ISO
β_1	Heart	Augmented inotropic and chronotropic effects	ISO > EPI $\geq$ NE
β_2	Blood vessels	Vasodilation	ISO > EPI >>> NE

EPI, epinephrine; ISO, isoproterenol; NE, norepinephrine; PE, phenylephrine.

observed cardiovascular responses (Figure 7.2). Arterial blood pressure is determined by the flow of blood through a vessel, which is ultimately determined by cardiac output and by the diameter or tone of that vessel, represented as peripheral vascular resistance. Information regarding the specific adrenergic receptors that play a role in cardiovascular regulation, their primary anatomical distributions in the vasculature and heart, the specific cardiovascular responses produced by their activation, and the order of potency of EPI, NE, isoproterenol, and phenylephrine are summarized in Table 7.5. This information provides the background required for explaining differences in cardiovascular response profiles to specific adrenergic agonists (Figure 7.2). In the examples described in this section each of the adrenergic receptor agonists have been administered as bolus injections over a short period of time.

Phenylephrine is a potent and selective agonist at α_1-adrenergic receptors. α_1-receptors are expressed in numerous vascular beds (e.g., visceral organs, skin, and skeletal muscle) and their activation by phenylephrine administration produces vasoconstriction of arterial smooth muscle, which in turn increases peripheral vascular resistance and reduces femoral blood flow and renal blood flow (Figure 7.2). In addition, phenylephrine administration produces venoconstriction, which reduces venous capacitance and increases venous return. The increase in arterial blood pressure is primarily due to the marked α_1-mediated increase in peripheral vascular resistance. The abrupt increase in arterial blood pressure secondary to phenylephrine administration activates the arterial baroreflex, which elicits a reflex-mediated increase in cardiac vagal nerve activity and a reduction in heart rate (bradycardia). α_1-receptors are not prominently expressed on cardiac cells involved in the regulation of cardiac rate or myocardial contractility; therefore phenylephrine administration does not elicit substantial direct effects on heart rate or cardiac output. However, from an integrative perspective phenylephrine administration does affect several of the physiological indices involved in the regulation of cardiac output, including: increased peripheral vascular resistance and afterload; increased venous return to the heart; and reduced heart rate via activation of the baroreflex.

Norepinephrine is an agonist at α-adrenergic (α_1 and α_2) and β_1-adrenergic receptors (and to a much lesser extent to β_2-adrenergic receptors). Activation of vascular α_1-adrenergic receptors by NE increases peripheral vascular resistance, as evidenced by decreases in femoral and renal blood flow (Figure 7.2). In addition, NE administration produces venoconstriction, which reduces venous capacitance and increases venous return. The activation of α_2-adrenergic receptors in vascular smooth muscle produces vasoconstriction and likely contributes to NE-induced increases in peripheral vascular resistance. β_1-adrenergic receptors are expressed in the heart, and activation of cardiac β_1-receptors by NE produces positive inotropic (increased cardiac contractility) and chronotropic (increased rate) effects. The increase in arterial blood pressure is mediated by combined vascular (α-adrenergic receptor-mediated vasoconstriction) and cardiac (increased cardiac output due to activation of β_1-adrenergic receptor) effects. The marked NE-induced increase in arterial blood pressure activates the arterial baroreflex, which elicits a reflex-mediated increase in cardiac vagal nerve activity and a reduction in heart rate. The reflex bradycardia does not necessarily lead to a reduction in cardiac output because of the direct effect of NE to activate cardiac β_1-receptors and increase myocardial contractility and stroke volume.

Epinephrine is a potent agonist at α-adrenergic (α_1 and α_2) and β-adrenergic (β_1 and β_2) receptors, and activation of vascular β_2-adrenergic receptors produces vasodilation. Therefore, EPI administration produces vasoconstriction and reduces blood flow in vascular beds that contain high concentrations of α-adrenergic receptors (e.g., visceral organs, cutaneous vessels), accounting for the EPI-induced reduction in renal blood flow (Figure 7.2). Some targets, such as the smooth muscle in the arterial vasculature supplying skeletal muscle, contain both β_2- and α-adrenergic receptors, and EPI-induced activation of β_2 receptors produces vascular vasodilation, whereas EPI-induced activation of α-adrenergic receptors produces vasoconstriction. In general, skeletal muscle vascular beds are often characterized by reduced peripheral vascular resistance in response to EPI administration (demonstrated as increased femoral blood flow in Figure 7.2), whereas EPI produces α-adrenergic receptor-mediated vasoconstriction in visceral vascular beds. Due to the competing vasoconstrictor and vasodilatory effects of EPI, the increase in peripheral vascular resistance to EPI administration is generally not as robust as that observed in response to NE administration (Figure 7.2). EPI is a prominent cardiac stimulant and activation of cardiac β_1-adrenergic receptors increases cardiac contractility, heart rate, and cardiac output. The initial effect of EPI administration is often characterized by a rapid increase in cardiac output (cardiac β_1-receptor activation), a marked increase in peripheral vascular resistance mediated by the activation of visceral α-adrenergic receptors, and an increase in arterial blood pressure, which in turn may elicit a baroreflex-mediated increase in cardiac vagal nerve activity and a transient reduction in heart rate. Subsequent activation of β_2-adrenergic receptors as EPI is distributed to peripheral sites, such as skeletal muscle vascular beds, attenuates increases in peripheral vascular resistance and arterial blood pressure.

Isoproterenol is a potent, nonselective β_1- and β_2-adrenergic receptor agonist that exerts little effect on α-adrenergic receptors; therefore blood pressure responses to this β-adrenoceptor agonist are a function of its effects on cardiac and peripheral vascular β-adrenergic receptors. The vascular response profile to isoproterenol administration is characterized by vascular vasodilation, an increase in blood flow to vascular beds that contain a high density of β_2-adrenergic receptors (skeletal muscle, as supported by the increase in femoral blood flow), modest β_2-adrenergic receptor-mediated vasodilation in visceral vascular beds (e.g., renal blood flow), and reduced peripheral vascular resistance (Figure 7.2). Because isoproterenol lacks affinity for α-adrenergic receptors, there is no pharmacological-induced vascular smooth muscle contraction; therefore isoproterenol produces a marked reduction in peripheral vascular resistance. Isoproterenol is a potent cardiac stimulant. Isoproterenol activation of cardiac β_1-adrenergic receptors increases cardiac output by increasing heart rate, mediated by direct activation of the sinus node, and by increasing contractility of myocardial cells. It is generally considered that β_1-adrenergic receptors are the predominate type of myocardial β-adrenergic receptor. Mean arterial blood pressure is typically reduced in response to isoproterenol secondary to the marked reduction in peripheral vascular resistance, despite the accompanying increase in cardiac output.

Comparing cardiovascular responses to specific catecholamines and select sympathomimetic drugs supports the concept that relative receptor affinity, direct receptor effects, receptor distribution, and intrinsic reflex adjustments are key components for predicting drug-associated physiological response profiles for a variety of organs and regulatory systems.

Clinical Applications of Adrenergic Receptor Agonists

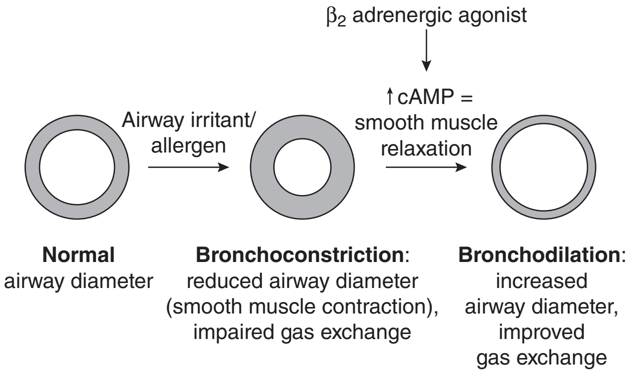
As stated previously, adrenergic receptors are distributed widely throughout many tissues and organ systems, and activation of these receptors facilitates a myriad of physiological responses. Selected clinical applications of sympathomimetics in specific conditions are described in this section as a framework for characterizing the pharmacodynamic effects of these drugs.

Adrenoceptor Agonists and Respiratory Physiology

A 15-year-old Quarter Horse mare presented with the clinical complaint of cough and increased abdominal effort during the expiratory phase of respiration. Physical examination revealed a heart rate of 44 beats per minute (normal; 36–44 beats per minute) and a respiratory rate of 20 breaths per minute (normal; 12–24 breaths per minute). Thoracic auscultation revealed increased bronchovesicular sounds and expiratory wheezes in all lung fields. In addition to an increased respiratory effort, the mare demonstrated prominent nostril flare (wide open nostrils) with expiration. Arterial blood gas analysis indicated hypoxemia as demonstrated by an arterial partial pressure of oxygen ($Pa0_2$) of 66 mmHg.

Based on the clinical findings, an immediate treatment protocol included the administration of aerosolized albuterol (selective β_2-adrenergic receptor agonist) (Rush et al., 1999). β_2-adrenergic receptors are present in bronchial smooth muscle, and activation of these receptors by β_2-agonists results in relaxation of bronchial smooth muscle and bronchodilation (Boushey, 2007; Cunningham, 2007). Approximately 10 minutes after albuterol administration, thoracic auscultation had improved substantially. Continued therapy included corticosteroid with albuterol, which was maintained over the course of 72 hours and the arterial partial pressure of oxygen level ($Pa0_2$) improved to 97 mmHg (Cornelisse et al., 2004; Boushy, 2007). In addition to improved oxygen delivery, the mare exhibited an improved respiratory effort demonstrated by resolution of her expiratory effort and nasal flare. The owner indicated the horse lived in a small pen with a round bale of hay that was stored outdoors.

This patient is suffering from recurrent airway obstruction, an allergic form of airway disease (Cunningham, 2007; Ainsworth and Cheetham, 2010). The condition is similar to asthma in humans. Airway obstruction results from hypersensitivity reaction to molds located in the forage. Following inhalation of molds, airway inflammation is induced in the form of neutrophil inflammation with marked mucous accumulation and airway smooth muscle contraction (Ainsworth and Cheetham,



β_2 adrenergic agonist
↑cAMP = smooth muscle relaxation
Airway irritant/ allergen
Normal
airway diameter
Bronchoconstriction:
reduced airway diameter (smooth muscle contraction), impaired gas exchange
Bronchodilation:
increased airway diameter, improved gas exchange

Figure 7.3 Airway irritants produce bronchoconstriction mediated via activation of inflammatory cascades and the parasympathetic nervous system (PSNS). The PSNS is responsible for maintaining baseline airway tone and activation of bronchial muscarinic receptors produces contraction of bronchial smooth muscle. Administration of a β_2-adrenergic receptor agonist and subsequent activation of bronchial smooth muscle β_2-adrenergic receptors increases intracellular cAMP levels with subsequent activation of cAMP-dependent protein kinase A, resulting in relaxation of bronchial smooth muscle.

2010). Therapeutic goals for affected individuals involve environmental management to reduce mold exposure and bronchodilation through the use of β_2-adrenergic receptor therapy. Corticosteroid therapy is aimed at reducing the hypersensitivity reaction (neutrophilic) to aerosolized allergens (Boushey, 2007; Ainsworth and Cheetham, 2010).

Control of bronchial smooth muscle tone depends on the integration of signals from several types of receptors that respond to chemical, mechanical, and physical stimuli (Cunningham, 2007; Guyton and Hall, 2011). The parasympathetic nervous system is responsible for maintaining baseline airway tone and activation of bronchial muscarinic receptors produces contraction of bronchial smooth muscle. On the other hand, activation of bronchial smooth muscle β_2-adrenergic receptors increases intracellular cAMP levels with subsequent activation of cAMP-dependent protein kinase A, which results in relaxation of bronchial smooth muscle (Figure 7.3).

Epinephrine and isoproterenol are potent bronchodilators, whereas NE exerts less of an effect due to its limited affinity for β_2-adrenergic receptors (Boushey, 2007). Several selective β_2-adrenergic receptor agonists are available for use in veterinary patients. Terbutaline is commonly used for small animal patients, can be administered parenterally or orally, and is useful for the treatment of airway constriction in dogs and cats (Boushey, 2007). In equine patients albuterol can be administered as a short-acting (1–2 hour) aerosolized bronchodilator for conditions that involve airway obstruction (bronchoconstriction) (Rush et al., 1999). Clenbuterol is an alternate bronchodilator prepared for oral administration as a syrup. A significant advantage of clenbuterol is a longer duration of action (12 hours). Clenbuterol is FDA approved for use in horses with airway constriction. It should be noted that clenbuterol is illegal for use in food-producing animals (Boushey, 2007; Ainsworth and Cheetham, 2010).

Sympathomimetics can be administered parenterally or by aerosol formulation to achieve rapid and effective bronchodilation for the treatment of allergic reactions or status asthmaticus. The selective β_2-adrenergic receptor agonists do not elicit the same number of additional physiological responses as do EPI and isoproterenol (Boushey, 2007; Guyton and Hall, 2011).

Arterial Blood Pressure Regulation and Sympathomimetics

A male Labrador retriever presented with a cranial cruciate rupture and was prepared for surgery. The patient was premedicated with hydromorphone, anesthesia was induced with propofol, and was maintained with isoflurane (volatile anesthetic) in oxygen. During the 20 minutes after initiation of isoflurane administration, systolic blood pressure gradually decreased from an initial level of 100 mmHg to 75 mmHg. The depth of anesthesia was determined to be appropriate, the heart rate was 92 beats/minute and the patient was normovolemic. What pharmacological interventions might be appropriate to treat the arterial hypotension in this patient?

When choosing a drug to treat hypotension, potential causes of the reduction in arterial blood pressure need to be considered. Isoflurane is a potent vasodilator, even at subanesthetic doses, and a reduction in peripheral vascular resistance is the predominant mechanism for the decrease in blood pressure. In addition, although cardiac output is preserved at low-dose isoflurane, the maintenance of surgical anesthesia for the type of surgery described for this condition may require higher doses of isoflurane, which are known to reduce cardiac output secondary to direct depressant effects on myocardial contractility. Under the conditions of this clinical case the isoflurane-induced hypotension would most effectively be ameliorated by a drug that can mediate increases in systemic vascular resistance and cardiac output; therefore, sympathomimetics that activate both α_1- and β_1-adrenergic receptors would be considered.

The drugs most frequently selected for treatment of hypotension in veterinary medicine under the described clinical situation would include dopamine, ephedrine, and dobutamine. Dopamine is an agonist at DA_1 receptors and the intravenous administration of low-dose dopamine (approximately, 0.5 to 2 μg/kg/min) promotes vasodilation of numerous vascular beds, including the renal and splanchnic vasculatures, an effect that would not be consistent with the express purpose of reversing isoflurane-induced hypotension. However, dopamine demonstrates complex, dose-dependent adrenergic receptor agonist properties. At moderate infusion rates (2 to 10 μg/kg/min) dopamine activates cardiac β_1-receptors, leading to increases in cardiac contractility, heart rate, and cardiac output. At higher rates of infusion (10 to 20 μg/kg/min), dopamine activates vascular α_1-adrenergic receptors, leading to vasoconstriction and increased peripheral vascular resistance. At the higher dose, dopamine remains an agonist at cardiac β_1-adrenergic receptors; therefore, high-dose dopamine infusion increases peripheral vascular resistance and enhances cardiac contractility, positioning dopamine as a suitable choice for isoflurane-induced hypotension. Dopamine has a short half-life and is given by a constant-rate intravenous infusion.

Ephedrine is a noncatecholamine drug that is an agonist at α_1-, β_1-, and β_2-adrenergic receptors, and can also induce the release of NE from postganglionic sympathetic nerve terminals. The cardiovascular effects of ephedrine have been shown to be dose dependent in isoflurane-anesthetized dogs (Wagner et al., 1993). Low-dose ephedrine (0.1 mg/kg) produces transient yet substantial increases in mean arterial pressure, cardiac index, and stroke volume, as well as decreases in heart rate and systemic vascular resistance. These data suggest that low-dose ephedrine may activate primarily cardiac β_1- and vascular β_2-adrenergic receptors. At a higher dose (0.25 mg/kg) ephedrine induces more marked and sustained increases in mean arterial pressure, cardiac index, and stroke volume, and also mediates an increase in systemic vascular resistance, suggesting that higher doses of ephedrine likely activates vascular α_1-adrenergic receptors. The combined cardiovascular effects produced by high-dose ephedrine make this drug an effective treatment option for isoflurane-induced hypotension.

Although at clinical doses dobutamine can act as an agonist at β_2- and α_1-adrenergic receptors, for the most part this drug demonstrates a relative selectivity for β_1-adrenergic receptors, especially those subserving changes in myocardial contractility (rather than cardiac rate). Thus, dobutamine administration increases myocardial contractility, cardiac index, and stroke volume. In this regard, dobutamine is particularly useful in treating low cardiac output flow states such as congestive heart failure or dilated cardiomyopathy. However, the rather modest agonistic properties at α_1-adrenergic receptors, at least in dogs, often make the use of dobutamine a less effective treatment option for isoflurane-induced hypotension (Rosati et al., 2007).

Epinephrine, NE, and phenylephrine are additional sympathomimetics that can increase arterial blood pressure, although they are not generally used under the conditions of isoflurane-induced hypotension. However, EPI is effective in life-threatening circumstances such as asystole or anaphylaxis. EPI is a potent cardiac stimulant and vasoconstrictive agent and can reverse the marked hypotension and cardiac irregularities associated with anaphylactic shock. Blood pressure responses to a given infusion rate of EPI are often associated with a substantial degree of interpatient variability; therefore, arterial blood pressure must be carefully monitored with EPI administration. EPI is a potent renal vasoconstrictor and can result in significant decreases in renal blood flow at higher doses. Additionally, some inhalation anesthetics, predominately halothane, can sensitize the heart to catecholamines. EPI decreases the refractory period and the heart is more susceptible to ventricular arrhythmias.

Because of its potent α_1-adrenergic receptor agonistic activity, NE is used clinically in hypotensive situations. NE administration induces marked constriction of arteries and veins and is used to support vascular resistance in circumstances such as vascular collapse secondary to sepsis. Like EPI, it is a potent constrictor of renal and mesenteric vascular beds, which may ultimately lead to decreased perfusion of those organ systems. Administration of selective α_1-adrenergic agonists, such as phenylephrine, produce peripheral vasoconstriction and are used in circumstances where cardiac output is adequate such as the hypotension resulting from spinal or epidural local anesthesia and subsequent block of sympathetic nerves.

Adrenergic Drugs and Urinary Incontinence

Adrenergic receptors are expressed at numerous sites in the urinary tract including the ureters (β_2 receptors), detrusor muscle of the bladder body (β_2 and β_3 receptors), bladder base (α_1 receptors), and the internal urethral sphincter (α_1 receptors). Stimulation of sympathetic nerves innervating these sites or activation of these receptors secondary to administration of sympathomimetics produces smooth muscle relaxation of the bladder body via β_2-adrenergic receptors (and β_3 receptors), and smooth muscle contraction at the bladder base and the internal urethral sphincter by activation of α_1-adrenergic receptors. The latter mechanism is the basis for treatment of urinary incontinence in veterinary patients using the α_1-adrenergic receptor agonists.

Urethral sphincter incompetence is the most common cause of acquired urinary incontinence in female dogs and cats. A single daily dose of phenylpropanolamine results in an increase in urethral pressure values and improved urinary continence in most affected dogs (Claeys et al., 2001). As expected, phenylpropanolamine administration can produce significant increases in arterial blood pressure, mediated by activation of vascular smooth muscle, and a baroreflex-mediated compensatory decrease in heart rate (Carofiglio et al., 2006). The consequences of phenylpropanolamine-induced increases in systemic vascular resistance and afterload should be considered when prescribing this drug for urinary incontinence.

Clinical Applications of Sympathomimetic-Induced Vasoconstriction

Drugs that are selective α-adrenergic agonists, or have potent α-adrenergic activity and minimal β_2-adrenergic effects, can cause significant vasoconstriction and are used for a number of clinical applications. These include the addition of EPI to local anesthetics to delay removal of the anesthetic from the site of injection, thereby prolonging its effect; the reduction of local perfusion to affect hemostasis in areas such as the nose or mouth; and the treatment of hypotension secondary to marked vasodilation but in the presence of normal or increased cardiac output, a response profile that occurs after sympathetic nerve blockade with spinal or epidural anesthesia.

α_1-adrenergic receptors are expressed on the smooth muscle of the splenic capsule and SNS activation to this target produces smooth muscle contraction, as does administration of sympathomimetics such as phenylephrine. Splenic smooth muscle contraction discharges red blood cells into the circulation and reduces the size of the spleen. Reduction of splenic size produced in response to the intravenous administration of the α_1-adrenergic selective receptor agonist phenylephrine is often used as part of the therapy for treatment of nephrosplenic entrapment in horses. This condition occurs when the left ventral and dorsal colon migrate between the spleen and the body wall and become entrapped over the nephrosplenic ligament, resulting in an obstruction of the large colon (Hardy et al., 2000). Phenylephrine administration reduces splenic area and thickness, and may increase the success of nonsurgical correction (Hardy et al., 1994). As expected, phenylephrine infusion increases peripheral vascular resistance and arterial blood pressure, and produces a marked baroreflex-mediated reduction in heart rate. The use of phenylephrine as a treatment option for nephrosplenic entrapment has been implicated in producing life-threatening internal hemorrhage in aged horses, and the use of this sympathomimetic as a treatment modality in older horses should be carefully considered (Frederick et al., 2010).

Peripheral and Central Sites Mediate Cardiovascular Responses to α_2-Receptor Activation

Circulating catecholamines do not readily cross the blood–brain barrier; however, certain sympathomimetic agents can gain access to the CNS and activate adrenergic receptors found in the brain and spinal cord. α_2-adrenergic receptor agonists (e.g., xylazine, detomidine, medetomidine, and dexmedetomidine) are routinely used in veterinary patients for sedation and analgesia. The sedative and analgesic effects of these agents are consistent with activation of central neural receptors and pathways. Accompanying the clinically desired sedative and analgesic effects are pronounced cardiovascular and sympathetic neural changes in response to administration of α_2-adrenergic selective receptor agonists (Kenney et al., 2014). The cardiovascular responses provide a window for characterizing physiological responses produced by activation of peripheral and central α_2-adrenergic receptor subtypes.

The α_2-adrenergic receptor family includes three subgroups: $\alpha_{2A,}$ $\alpha_{2B,}$ and $\alpha_{2C.}$ α_2-adrenergic receptors are present in vascular smooth muscle, on the terminals of postganglionic sympathetic nerve fibers, and in the central nervous system, including in the brainstem. The intravenous administration of selective α_2-adrenergic receptor agonists produce a biphasic cardiovascular profile, an initial transient hypertension followed by a longer lasting hypotension. The following description of the biphasic cardiovascular response is based on the intravenous administration of dexmedetomidine, and is representative of responses induced by α_2-adrenergic selective receptor agonists.

Activation of α_2-adrenergic receptors by intravenous dexmedetomidine administration produces vasoconstriction of arterial smooth muscle, which increases peripheral vascular resistance and produces an immediate increase in arterial blood pressure. It is thought that the dexmedetomidine-induced contraction of vascular smooth muscle is mediated by activation of α_{2B}-adrenergic receptors. The abrupt increase in arterial blood pressure activates the arterial baroreflex, which elicits a reflex-mediated increase in cardiac vagal nerve activity and a reduction in heart rate. Circulating dexmedetomidine rapidly gains access to CNS α_2-adrenergic receptors and activation of brainstem receptors produce inhibition of sympathetic nerve outflow and activation of parasympathetic nerve outflow. It is thought that the central neural effects of dexmedetomidine on sympathetic and parasympathetic neural circuits are mediated by activation of α_{2A}-adrenergic receptors. The dexmedetomidine-induced hypotensive response is mediated by the sustained reduction in sympathetic nerve outflow, as well as the sustained increase in parasympathetic nerve outflow, which mediates a reduction in heart rate.

Ophthalmology and Adrenergic Agonists

A 9-year-old golden retriever presented with cloudy lenses and the owner reported the animal had decreased vision. The ophthalmic examination revealed bilateral advanced immature cataracts. To facilitate intraoperative mydriasis (pupillary dilation), the selective α_1-adrenergic receptor agonist, phenylephrine, is used in dilation protocols for dogs prior to cataract surgery. α_1-adrenergic receptors are expressed on the radial dilator muscle of the iris (iris dilator muscle) and on conjunctival blood vessels. SNS activation to this target causes mydriasis, as does α_1-adrenergic receptor activation by sympathomimetics such as phenylephrine. Following topical application, phenylephrine produces contraction of the smooth muscle of the conjunctival blood vessels and contraction of the iris dilator muscle, causing blanching of the conjunctival vasculature and pupillary dilation, respectively. Topical phenylephrine should be used with caution in small patients due to the potential for phenylephrine to enter the systemic circulation and induce arterial hypertension secondary to activation of peripheral vascular α_1-adrenergic receptors (Pascoe et al., 1994). Phenylephrine is commercially available in 2.5% and 10% solutions.

A dilute solution of phenylephrine may also be used in the neuroanatomic localization of Horner's syndrome, an oculosympathetic palsy (Webb and Cullen, 2013). After application of a dilute solution of phenylephrine to both eyes in unilateral postganglionic Horner's syndrome, the affected pupil should dilate within 20 minutes and other clinical signs (ptosis, enophthalmia, and third eyelid elevation) will improve or completely resolve.

Apraclonidine and brimonidine are α_2-agonists that have intraocular pressure lowering effects in humans, secondary to increasing the outflow of aqueous humor from the eye. These medications are not recommended for veterinary patients due to systemic side effects and lack of significant intraocular pressure lowering effects (Miller and Rhaesa, 1996; Gelatt and MacKay, 2002).

Use of β-Adrenergic Agonists in Food Production

Beta-adrenergic receptor agonists (βAA) have been used as growth promotion agents for livestock in the United States since 1999 when ractopamine hydrochloride was approved in swine (FDA, 1999). Since that time, ractopamine has been approved for use in cattle and turkeys and a second βAA, zilpaterol, was approved for use in cattle in the United States, Mexico, Canada, and South Africa (FDA, 2003; FDA, 2006). Ractopamine is primarily a β_1-adrenergic receptor agonist with some β_2-receptor activity. Zilpaterol is primarily a β_2-adrenergic receptor agonist. It is also important to note that not all βAA are approved for use in food animals. In the United States, it is illegal to feed a βAA or any other drug in a manner that is inconsistent with its labeling as approved by the FDA. Extra-label drug use is strictly prohibited. These drugs are fed at the end of the animals feeding period only. The use of these drugs in food animals is further discussed in Chapter 52.

The muscle growth in response to βAA treatment appears to be a true muscle hypertrophy, such that muscle fibers increase in diameter due to increased protein synthesis and decreased protein degradation without the incorporation of additional DNA from satellite cells (Yang and McElligott, 1989). However, with longer duration of βAA administration the rate of hypertrophy cannot be maintained without additional DNA and the responsiveness to the βAA is dampened and the accretion of skeletal muscle decreases. The response of muscle cells to βAA stimulation is highly dependent on receptor presence, which is influenced by animal maturity and receptor density, which can be reduced with chronic βAA administration. Additionally, the muscle hypertrophy within the carcass is not evenly distributed, as skeletal muscles that are used for locomotion, which typically have an increased blood supply, have a greater degree of hypertrophy compared to apaxial muscles (Hilton et al., 2010). Muscle fiber types are also differentially affected by β_2AA administration as the increase in muscle fiber diameter is greater in type IIA fibers compared with type I fibers. Beta receptor specificity of skeletal muscle varies between species used for food production. Ruminants tend to have an increased number of β_2-adrenergic receptors than other species. The distribution of subtypes of receptors also varies with the age of the animal, with a more pronounced response to β_2AA in yearling cattle, when compared to calves or fetal responses (Beermann, 2002; Johnson et al., 2014).

Glycogenolysis is increased by βAA stimulation of muscle (Etherton, 1994). Glycogenolytic effects are induced by the phosphorylation of glycogen phosphorylase, which converts glycogen, an intracellular stored form of glucose, to monomeric glucose-6-phosphate. Glucose-6-phosphate is a substrate source for glycolysis, or anaerobic respiration, resulting in the production of ATP and pyruvate. Pyruvate will then enter the Krebs cycle and undergo aerobic respiration, assuming that enough cellular oxygen is available. If the cell is in a hypoxic state, pyruvate will be converted to lactate by lactate dehydrogenase. Lactate will then accumulate and be removed from the cell via blood circulation. The end result of βAA-mediated glycogenolysis is to make an energy source stored within the muscle cell rapidly available.

In adipose cells, βAA promote lipolysis associated with stimulating triacylglycerol hydrolysis and inhibiting lipogenesis stimulated through the β-receptor–G protein–cAMP–PKA pathway (Lafontan et al., 1988; Bergen, 2001; Johnson et al., 2014). The βAA-induced increase in cAMP results in the phosphorylation of acetyl-CoA carboxylase inhibiting the de novo biosynthesis of fatty acids. The net response of adipose tissue to βAA is lipolytic and causes a release of fatty acids, which may be used as an energy source by conversion to acetyl-CoA (Blum and Flueckiger, 1988; Johnson et al., 2014). High concentrations of acetyl-CoA can inhibit conversion of pyruvate to acetyl-CoA, forcing pyruvate to be metabolized to lactate by lactate dehydrogenase and potentially increasing metabolic acidosis in cases where lactic acidosis is present, such as hypoxic situations (Haffner and Kendall, 1992).

β-adrenergic receptor agonists exert significant cardiovascular effects as described earlier in this section. The use of ractopamine and zilpaterol has been shown to increase heart rate in cattle, with the most significant increase at the beginning of the feeding period.

Adrenergic-Receptor Antagonists

The physiological effects produced by activation of the SNS or the administration of sympathomimetic drugs can be diminished by blocking adrenergic receptors (adrenoceptor antagonists), decreasing the amount of NE released presynaptically, or suppressing sympathetic outflow from central sympathetic neural circuits. Drugs that inhibit the interaction of NE, EPI, and other sympathomimetics with α- and β-adrenergic receptors are termed adrenergic receptor antagonists or adrenoceptor antagonists.

Adrenergic receptor antagonists demonstrate selectivity and specificity for the various adrenergic receptors, and drugs are classified based on their antagonism of α- or β-adrenergic receptors. Antagonism of peripheral dopaminergic receptors is of little clinical relevance in veterinary medicine at the present time. Blockade of dopaminergic receptors in the CNS have significant clinical relevance and these drugs are discussed in Chapter 9. The relative selectivity for adrenergic receptor antagonists are presented in Table 7.6.

Table 7.6 Classification of adrenergic receptor antagonists and their relative selectivity for specific adrenergic receptors

Drugs	Receptor selectivity
Alpha antagonists	
Prazosin, Terazosin, Doxazosin	$\alpha_1 >>>> \alpha_2$
Phenoxybenzamine	$\alpha_1 > \alpha_2$
Phentolamine	$\alpha_1 = \alpha_2$
Atipamezole, Yohimbine, Tolazoline	$\alpha_2 >> \alpha_1$
Mixed antagonists	
Carvedilol	$\beta_1 = \beta_2 \geq \alpha_1 > \alpha_2$
Beta antagonists	
Propranolol, Timolol	$\beta_1 = \beta_2$
Metoprolol, Atenolol, Esmolol, Betaxolol	$\beta_1 >>> \beta_2$

Alpha-Adrenergic Receptor Antagonists

Alpha-adrenoceptor antagonists are a chemically heterogeneous and structurally diverse group of drugs. Some of the more clinically relevant groups include β-haloethylamine alkylating agents (e.g., phenoxybenzamine), imidazoline analogs (e.g., phentolamine and tolazoline), piperazinyl quinazolines (e.g., prazosin), and indole derivatives. These drugs are predominantly competitive antagonists at α-adrenergic receptors, with the exception of phenoxybenzamine which irreversibly binds to the α-adrenergic receptor. The relative receptor affinity of individual α_1- and α_2-receptor antagonists varies markedly, and recent research advances have developed drugs that discriminate among the receptor subtypes. Additionally, the phenothiazine tranquilizers (e.g., acepromazine) demonstrate substantial α-adrenergic receptor blocking effects, but since this is generally considered a side effect of these drugs, as opposed to an indication for their use, these drugs will not be discussed in this chapter.

Cardiovascular Effects

Some of the most significant clinical and therapeutic effects, particularly of the α_1-antagonists, target the cardiovascular system. Systemic administration of α_1-adrenergic receptor antagonists produces dilation of both arterial and venous vessels, resulting in reduced blood pressure secondary to decreases in peripheral vascular resistance. As expected, administration of α_1-adrenergic receptor antagonists block or eliminate the vasoconstriction and blood pressure responses produced by exogenous administration of sympathomimetic drugs or neurotransmitters. For example, increases in peripheral vascular resistance and subsequent elevations in blood pressure produced by phenylephrine (selective α_1-adrenergic receptor agonist) administration are completely eliminated by pretreatment with an α_1-adrenergic antagonist. Following pretreatment with an α_1-adrenergic receptor antagonist, increases in peripheral vascular resistance to NE administration are eliminated, which markedly attenuates NE-induced increases in arterial blood pressure despite its effect to activate cardiac β_1-adrenergic receptors and increase heart rate and cardiac contractility. Furthermore, following pretreatment with an α_1-adrenergic receptor antagonist, administration of EPI may induce a reduction in peripheral vascular resistance and marked vasodilation mediated by activation of β_2-adrenergic receptors, resulting in decreased levels of arterial blood pressure. This effect is known as EPI reversal and can occur not only with exogenous administration of the sympathomimetic following administration of an α_1-adrenergic receptor antagonist, but may also occur when administering an α_1-adrenergic receptor antagonist to a patient with high circulating levels of EPI.

Noncardiovascular Effects

Activation of sympathetic nerves innervating the urethra produces contraction of urethral smooth muscle by activation of α_1-adrenergic receptors. α_1-adrenergic receptor antagonists decrease resistance to urine flow. α_{2B}-adrenergic receptors have a role in platelet aggregation; however, the clinical significance of blocking these receptors and the role it might play in antiaggregant therapy is not well understood. α_2-adrenergic receptors inhibit insulin secretion from pancreatic islet cells and antagonism of these receptors may stimulate insulin release. Other effects produced by α-adrenergic receptor antagonists include protrusion of the third eyelid, miosis, and nasal stuffiness. α_2-adrenergic receptor agonists are frequently used to provide sedation and analgesia to veterinary patients, and there are several α_2-adrenergic receptor antagonists, that can reverse the sedation mediated by the α_2-adrenergic receptor agonists. Specific physiological effects of available α_2-adrenergic receptor antagonists will be discussed under the section on specific agents.

Specific Agents and Clinical Uses

Nonselective α_1-α_2-Antagonists

Phenoxybenzamine and phentolamine are examples of α-adrenergic antagonists with effects at both α_1- and α_2-adrenergic receptors. There are few clinical indications for the use of phentolamine in veterinary medicine and formulations of this drug are no longer consistently available in the United States.

Phenoxybenzamine binds covalently to α-adrenergic receptors and produces an irreversible block. Restoration of physiological responses to activation of α-adrenergic receptors following phenoxybenzamine administration requires the synthesis of new α-adrenergic receptors. The α-adrenergic antagonistic effects of phenoxybenzamine are more substantial with α_1- than α_2-adrenergic receptors. Phenoxybenzamine demonstrates a variety of other pharmacological effects including inhibiting the reuptake of NE at presynaptic nerve terminals and acting to various degrees as an antagonist at histamine, acetylcholine, and serotonin receptors. The predominant, and perhaps only, use of phenoxybenzamine in veterinary medicine is to manage the symptoms of catecholamine excess in the treatment of patients with a pheochromocytoma (Herrera et al., 2008; Agrawal et al., 2014).

Phenothiazine tranquilizers are also potent, nonselective α-adrenergic receptor antagonists. The CNS effects of these drugs underlie their use as tranquilizers; however, the decrease in peripheral vascular resistance secondary to antagonism of α-adrenergic receptors is clinically significant and should be considered when selecting these drugs for tranquilization or anesthetic premedication. Similarly, the tetracylic antidepressant trazodone, used for its sedative properties in dogs, can antagonize α_1-adrenergic receptors.

Selective α_1-Antagonists

Prazosin is a competitive antagonist with a marked selectivity for the α_1-adrenergic receptor. Historically, prazosin has been used for the treatment of hypertension or to reduce afterload in patients with heart failure, but there are now more efficacious therapies. Currently, prazosin is used to decrease resistance to urine flow in the proximal and prostatic urethra in dogs with functional urethral obstruction, prostatic hyperplasia, and idiopathic vesicourethral reflex dyssynergia, or to facilitate voiding in animals with upper motor neuron bladders (detrusor–external sphincter dyssynergia) due to spinal trauma or intervertebral disc disease (Fischer et al., 2003; Haagsman et al., 2013). The efficacy of this drug in the treatment of urethral obstruction in cats is debated because smooth muscle is confined to the proximal third of the cat urethra, whereas urethral obstructions in these animals generally occur in the distal urethra, which is composed of skeletal muscle (Hetrick and Davidow, 2013; Lulic et al., 2013). Terazosin, doxazosin, and alfuzosin are reversible α_1-adrenergic receptor antagonists with similar physiological effects to prazosin, but with different pharmacokinetic profiles. Specific information regarding the use of these drugs in veterinary patients is limited.

Tamsulosin and silodosin are α_1-adrenergic receptor antagonists that demonstrate a degree of α_1-adrenergic receptor subtype selectivity. Tamsulosin is a second-generation α_1-adrenergic receptor antagonist that was developed with the goal of decreasing the frequency of orthostatic hypotension. Tamsulosin has a higher affinity for α_{1A} and α_{1D} receptors than for the α_{1B} subtype. The α_{1A}-adrenergic receptor subtype is a primary adrenergic receptor subtype in the urethra and prostate of humans and dogs, whereas the α_{1B}-adrenergic receptor subtype is a principal subtype in vascular smooth muscle in these species (Kobayashi et al., 2009). Silodosin is a third-generation, highly selective α_{1A} receptor antagonist. Dogs with and without prostatic hyperplasia demonstrated similar effects between silodosin and tamsulosin on decreasing intraurethral pressure, but silodosin had less of an effect on blood pressure (Kobayashi et al., 2009). Silodosin suppresses phenylephrine-induced increases in intravesical ureteral pressure in dogs and may facilitate passage of distal ureteral stones (Kobayashi et al., 2010). Although orthostatic hypotension is not as clinically significant in veterinary patients, the potential for effects on peripheral vasculature when using these drugs should be considered.

Selective α_2-Antagonists

Yohimbine, tolazoline, and atipamezole are α_2-adrenergic receptor antagonists that are used to reverse the sedative effects of α_2-adrenergic agonists such as xylazine, medetomidine, dexmedetomidine, detomidine, and romifidine. Reversal of α_2-agonist-mediated sedation and off-label therapy of certain drug intoxications are currently the only therapeutic indications for these drugs in veterinary medicine.

Yohimbine was the prototype for selective α_2-adrenergic receptor antagonists and is an indolealkylamine alkaloid that is found in the bark of the tree *Pausinystalia yohimbe* and in *Rauwolfia* root. Yohimbine also demonstrates a degree of antagonistic activity at serotonin receptors. Yohimbine is used in veterinary patients to reverse sedation from α_2-adrenergic agonists, although less frequently in small animal patients since the introduction of atipamezole. The efficacy of yohimbine for reversal of xylazine sedation in cattle is variable.

Tolazoline belongs to the synthetic group of competitive α_2-adrenergic receptor antagonists known as the imidazoline derivatives. Tolazoline is a mixed α_1- and α_2-adrenergic receptor antagonist, and the approved product, Tolazine Injection, is licensed for reversing xylazine in horses. This product is used off-label to reverse other α_2-adrenergic agonists in equids, such as detomidine, and for the reversal of α_2-agonist sedation in other large animal species and wildlife, where the cost of atipamezole may be a concern (Powell, 1998). The use of tolazoline or other α_2-adrenergic receptor antagonists to reverse detomidine sedation is incomplete and transient.

Atipamezole is an α_2-adrenergic receptor antagonist with an imidazole structure and a binding affinity and α_2/α_1 selectivity ratio much higher than those of yohimbine or tolazoline. Atipamezole is not selective for subtypes of α_2-adrenergic receptors (Pertovaara et al., 2005). Atipamezole was originally approved to reverse the sedative and analgesic effects of medetomidine hydrochloride. Atipamezole rapidly reverses sedation induced by α_2-adrenoceptor agonists, at one-tenth the dose required for yohimbine. Atipamezole at clinically relevant doses causes few cardiovascular effects despite the potential increase in NE following blockade of presynaptic α_2-adrenergic receptors. Atipamezole reverses the bradycardic effects produced by α_2-adrenergic receptor agonists. Atipamezole has been used off-label in dogs to treat intoxication by imidazoline decongestants (e.g. oxymetazoline, tetrahydrozoline, xylometazoline) that are α_2-adrenoceptor agonists used topically for relief of nasal congestion or conjunctival redness. Atipamezole has also been used off-label to treat intoxication from the insecticide/acaricide, amitraz, which is an α_2-adrenergic receptor agonist (Bahri, 2008).

Clinical Use of α-Adrenergic Receptor

It is not uncommon for small animal patients to develop a urethral obstruction, a condition that is often relieved with a urethral catheter. Unfortunately, recurrence of urethral obstruction following removal of the urinary catheter is a frequent complication (Hetrick and Davidow, 2013). Activation of sympathetic nerves to the bladder facilitates relaxation of the bladder body smooth muscle through activation of β_2- and β_3-adrenergic receptors, and enhances contraction of the smooth muscle of the proximal urethra by activation of α_1-receptors.

Urethral spasm is thought to play a role in urethral obstruction recurrence and drugs that mediate urethral smooth muscle relaxation by α_1-adrenergic receptor blockade are a useful component of postobstruction therapy. The two most frequently used drugs in veterinary medicine are phenoxybenzamine and prazosin. Prazosin has a higher α_1-adrenergic receptor affinity, and administration of prazosin to dogs results in a greater reduction of urethral pressure than phenoxybenzamine (Fischer et al., 2003).

Important limitations to the use of α_1-adrenergic receptor antagonists for urethral relaxation are the cardiovascular effects. Vascular smooth muscle tone is reduced with α_1-adrenergic receptor blockade and significant decreases in systolic, diastolic, and mean arterial blood pressure can occur. Newer selective α_1-adrenergic receptor antagonists, such as silodosin, have less of an effect on blood pressure than nonselective antagonists like prazosin, but clinical data for use of α_{1A} selective antagonists in veterinary medicine at this point is limited.

Beta Adrenergic Receptor Antagonists

Beta-adrenergic receptor antagonists are used widely in human medicine because of their efficacy in the treatment of hypertension, ischemic heart disease, congestive heart failure, and certain cardiac arrhythmias. While some of these clinical entities are also indications for the use of β-adrenergic antagonists in veterinary patients, the routine use of β-blockers in veterinary medicine remains somewhat controversial based on the relative dearth of information determining the clinical efficacy of these drugs in veterinary patients.

β-adrenergic receptor antagonists are structurally similar to catecholamines and competitively reduce receptor occupancy by catecholamines and other β-adrenergic agonists. Most of the available drugs are pure antagonists; however, there are several that are partial β-adrenergic receptor agonists (e.g., pindolol and acebutolol). These drugs can cause partial activation of β receptors, although not to the level of full agonists such as EPI, and inhibit the activation of β-adrenergic receptors in the presence of high levels of EPI and NE. This effect of some β-adrenergic antagonists is often

Table 7.7 Pharmacodynamic characteristics of adrenergic receptor antagonists commonly used in veterinary medicine

Drugs	β-Receptor selectivity	α_1-Receptor block	Intrinsic sympathetic activity	Local anesthetic activity
Atenolol	β_1	No	No	No
Betaxolol	β_1	No	No	Slight
Carvedilol	None	Yes	No	No
Celiprolol	β_1	No	Yes	No
Esmolol	β_1	No	No	No
Metoprolol	β_1	No	No	Yes
Pindolol	None	No	Yes	Yes
Propranolol	None	No	No	Yes
Sotalol	None	No	No	No
Timolol	None	No	No	No

referred to as intrinsic sympathetic activity (ISA). Drugs with ISA maintain slight basal stimulation of the β_1- and β_2-adrenergic receptors, and this modest β-mediated activity may prevent profound bradycardia or negative inotropy in the resting heart, constriction of bronchioles, or up-regulation of β-adrenergic receptors that can result from long-term therapy with β-adrenergic receptor antagonists. Whether there are clinical advantages or indications for using a drug with ISA remains unclear.

Some β-adrenergic antagonists exhibit membrane-stabilizing activity, similar to local anesthetics, and other β-adrenoceptor blockers are classified as inverse agonists (e.g., carvedilol). Receptors exist in a conformational equilibrium between inactive and active states and this equilibrium shifts with the binding of a ligand. Inverse agonists favor the inactive conformation and will decrease the propensity of the receptor to assume a conformation that is required for stimulation of cAMP, thereby reducing the constitutive activity of the β-adrenergic receptor (Khilnani and Khilnani, 2011).

β-adrenergic receptor antagonists are frequently categorized by their affinity for β-adrenergic receptor subtypes, presence or absence of ISA, and their membrane stabilization effects (Table 7.7). Drugs differ in their relative affinities for β_1 and β_2 receptors. Some have higher affinity for β_1- than for β_2-adrenergic receptors, but none of the clinically available drugs are completely specific for a given β-adrenergic receptor, and the ultimate clinical effect will be dose dependent.

Cardiovascular Effects

The antagonism of β-adrenergic receptors can substantially affect cardiovascular regulation, although there are numerous factors that can influence these responses, including: species differences, human and animal differences, the presence of background cardiovascular disease, and the specific antagonist administered. General cardiovascular effects are reviewed here. Antagonism of cardiac β-adrenergic receptors slows atrioventricular conduction, and produces negative inotropic and chronotropic effects, which may mediate a reduction in cardiac output (Muir et al., 1996). Beta-blocking drugs when administered chronically may reduce blood pressure in hypertensive patients, although they generally do not reduce blood pressure in normotensive patients. It is important when reviewing the effects of individual drugs to distinguish between effects in normal subjects and subjects with cardiovascular disease. Increased peripheral vascular resistance is often an acute effect observed following administration of β-adrenergic receptor antagonists, an effect that is mediated in part by blockade of vascular β_2 receptors. However, with long-term use of β-adrenergic receptor antagonists, peripheral vascular resistance returns to initial values or decreases in patients with hypertension. The mechanism for this response is not well understood, but may involve an effect on the release of renin from the juxtaglomerular apparatus. Activation of the SNS innervation to the kidney increases renin release via activation of β_1-adrenergic receptors, and this effect is reduced with β-adrenergic receptor blockade. In addition, some β-blockers, such as labetalol and carvedilol, also demonstrate antagonistic properties at α_1-adrenergic receptors, which may contribute to a reduction in peripheral vascular resistance.

Pulmonary Effects

Nonselective β-adrenergic receptor antagonists will block β_2-adrenergic receptors in bronchial smooth muscle leading to bronchoconstriction and increased airway resistance. In normal subjects this effect is minimal but in patients with asthma or chronic obstructive pulmonary disease it can be life-threatening. The implications of this in veterinary medicine have not been explored. With regards to recurrent obstructive pulmonary disease, aerosol administration of propranolol or atenolol during an acute airway obstruction can reduce dynamic compliance, whereas during clinical remission the drugs may exert little effect. The clinical indications for the use of β-adrenergic receptor antagonists in equine patients are few, and the effects of β-adrenergic receptor antagonists in cats with feline lower airway disease have not been studied.

Effects on the Eye

Topical administration of β-adrenergic receptor antagonists reduce intraocular pressure by blocking NE released from sympathetic nerve endings from acting on β-adrenergic receptors located on the ciliary epithelium, thereby mediating a decrease in aqueous humor production.

Metabolic and Endocrine Effects

β-adrenergic receptor antagonists inhibit the activation of lipolysis and glycogenolysis produced by catecholamines and sympathomimetic drugs. Nonselective β-adrenergic receptor antagonists may delay recovery from hypoglycemia in patients with type 1 diabetes mellitus, an effect that appears to be less severe in type 2 diabetic patients. β_1-selective adrenergic receptor antagonists are less likely to inhibit the recovery of blood glucose levels from an acute bout of hypoglycemia.

Specific Drugs

Beta-adrenergic receptor antagonists are classified as nonselective β-adrenergic receptor antagonists (first generation), β_1-selective receptor antagonists (second generation), and nonselective or subtype selective β-adrenergic receptor antagonists with additional cardiovascular actions unrelated to β-adrenergic receptor blockade (third generation). The receptor specificity and other nonadrenergic-related effects of several β-adrenergic receptor antagonists are summarized in Table 7.7. Clinically relevant information for many of these drugs is lacking due to the fact that relatively few controlled trials have been completed in animals with naturally occurring disease. Drugs that have been used most frequently in veterinary patients include propranolol, atenolol, esmolol, metoprolol, and carvedilol.

Nonselective β-adrenergic Receptor Antagonists

Propranolol is the prototype nonselective β-adrenergic receptor antagonist and in veterinary medicine has historically been used in the treatment of tachyarrhythmias, hypertension, hypertrophic and obstructive cardiomyopathies, and to treat the cardiovascular consequences of thyrotoxicosis or pheochromocytoma. Propranolol is a competitive antagonist with no intrinsic sympathomimetic activity. It does have membrane-stabilizing activity, but the therapeutic significance of this is not well defined.

Propranolol is well absorbed from the gastrointestinal tract following oral administration, is lipophilic, and demonstrates a large volume of distribution. However, this drug undergoes extensive hepatic metabolism, therefore its bioavailability is low. With the development of more selective β-adrenergic receptor antagonists, the use of propranolol is rarely indicated.

Selective β_1-Adrenergic Receptor Antagonists

Metoprolol is a selective β_1-adrenergic receptor antagonist that exhibits no intrinsic sympathomimetic activity. Metoprolol has a large volume of distribution and undergoes extensive oxidative metabolism in the liver, with less than 10% excreted unchanged in the urine. The elimination half-life of metoprolol in small animals is much shorter than that reported in people. Atenolol is a selective β_1-adrenergic receptor antagonist with no intrinsic sympathomimetic activity, a half-life that is longer than that of metoprolol, a large volume of distribution, and is characterized by minimal hepatic metabolism. Esmolol is an ultra-short-acting β_1-adrenergic receptor subtype selective antagonist with a half-life of about 10 minutes. Steady-state concentrations are quickly achieved during continuous intravenous infusions and its effects are terminated rapidly when the infusion is discontinued.

Third-Generation Nonselective Antagonists

Carvedilol is a nonselective β-adrenergic receptor antagonist and demonstrates modest α_1-adrenergic receptor antagonist properties. Carvedilol attenuates oxygen free radical-initiated lipid peroxidation and has antiproliferative effects. Carvedilol demonstrates membrane-stabilizing activity but no ISA. Carvedilol is rapidly absorbed following oral administration and is extensively metabolized.

Clinical Uses of β-Adrenergic Receptor

Acquired Cardiac Disease in Dogs

Studies in heart failure patients have demonstrated that β-adrenergic receptor antagonism with β_1-selective antagonists or the third-generation antagonist, carvedilol, reduce mortality and/or hospitalization and increase quality of life (Packer et al., 1996; Bristow, 1997). Initially the use of β-adrenergic receptor antagonists in the treatment of heart failure was avoided due to their negative inotropic effects, and the potential for bradycardia, cardiac failure, hypotension, and bronchospasm. However, the availability of more β_1-adrenergic receptor selective drugs or those with additional nonadrenergic related cardiac effects have reduced the potential for some of these complications.

Chronic valvular heart disease, specifically chronic mitral valvular disease, is the most common cause of heart disease and congestive heart failure in dogs, followed by dilated cardiomyopathy (DCM). Neuroendocrine mechanisms that occur during the development of heart failure include stimulation of the SNS, activation of the renin–angiotensin system, and release of vasopressin. High circulating concentrations of NE are evident in dogs with clinical chronic degenerative atrioventricular valve disease (Ware et al., 1990) and in experimental models of mitral valve regurgitation (MR) (Tsutsui et al., 1994). Increased cardiac sympathetic nerve activity precedes the increase in circulating NE in subjects with primary MR. Although beneficial in the early stages to preserve inotropy, chronic sympathetic activation and elevated catecholamine levels can lead to cardiac hypertrophy and remodeling, myocyte necrosis, chronically elevated heart rate, elevated afterload, and cardiac arrhythmias. A protective adaptation of downregulation of β_1-adrenoceptors has been described. One of the proposed mechanisms of systolic dysfunction seen with primary MR from chronic mitral valve disease (CMVD) is related to the increased sympathetic activity which results in a reduction of the number of cardiomyocytes and the number of contractile elements within each cardiomyocyte.

It has been proposed that β-adrenergic receptor antagonists might be a beneficial therapy in dogs with CMVD. One study reported a significant improvement of the left ventricular function in dogs with experimentally induced MR treated with the β antagonist atenolol (Nemoto et al., 2002). The administration of atenolol resulted in a decrease in cardiac interstitial NE in the experimental dogs. However, in a retrospective study of dogs with acquired DCM or CMVD, metoprolol administration was associated with no significant differences in cardiac dimensions as measured with echocardiography (Rush et al., 2002).

The effects of orally administered carvedilol were studied prospectively in dogs with mitral valve disease (Marcondes-Santos et al., 2007). The primary end points involved quality of life and sympathetic activation with secondary end points involving echocardiographic variables. The study period was 3 months and there was concurrent administration of benazepril or benazepril and digoxin depending on the severity of disease. The dogs treated with carvedilol had improvement in quality of life scores and a modest reduction in systolic blood pressure. Carvedilol did not improve the sympathetic activation and echocardiographic variables over the 3 months of treatment. Similarly, in a prospective study of dogs with DCM, there was no difference in echocardiographic and neurohormonal variables in the group treated with carvedilol. Additionally, there was no difference in owner-perceived quality of life (Oyama et al., 2007).

Administration of β-adrenergic antagonists is reported to initially worsen hemodynamics and contractile function in dogs with experimental MR. Acute decompensation has been reported in people and dogs with heart failure immediately after initiation of therapy (Kittleson and Hamlin, 1981; Fung et al., 2003). More recently, the phosphodiesterase III inhibitor, pimobendan, has shown clear benefits in dogs with CMVD or DCM and the use of β antagonists in these patients is now seldom indicated (Haggstrom et al., 2008; O'Grady et al., 2008).

Hypertrophic Cardiomyopathy and Ventricular Outflow Obstruction

Hypertrophic cardiomyopathy (HCM) is the most common cardiac disease in cats and a significant percentage of cats with HCM will develop dynamic obstruction of the left ventricular outflow tract (LVOT). HCM and hypertrophic obstruction cardiomyopathy (HOCM) are characterized by concentric ventricular hypertrophy, dysfunction during diastole, and elevation of left ventricular end–diastolic pressure and left atrial pressure. Obstruction of the LVOT can be due to a single cause or a combination of causes that include asymmetric ventricular septal hypertrophy and anterior (cranial) motion of the mitral valve during systole (SAM).

The most commonly prescribed medications used to reduce dynamic LVOT obstruction in cats with HCM are β-adrenergic receptor antagonists, particularly atenolol. Echocardiographic evaluation of cats with HCM or HCOM given a single dose of atenolol revealed decreases in heart rate, peak velocity in the LVOT, systolic fractional shortening, and left atrial size. Atenolol consistently reduced, and in some cases relieved, LVOT obstruction (Blass et al., 2014). There are conflicting reports on the prognostic importance of SAM in cats with HCM and whether treatment with atenolol should be instituted in preclinical HCM remains controversial. It would be predicted that the negative chronotropic and inotropic effects would reduce peak velocity of blood flow at the LVOT which would, theoretically, decrease the force on the mitral valve leaflets against the septum and delay the development of SAM. The negative inotropic effect would decrease systolic fractional shortening and the potential for dynamic obstruction from the hypertrophied ventricular septum.

Subaortic stenosis (SAS) in dogs is a congenital cardiac abnormality that causes varying degrees of LVOT obstruction. The disease is characterized by an abnormal ridge of fibrous tissue below the aortic valve which results in a decreased cross-sectional area of the LVOT. The severity of disease and prognosis varies depending on the degree of stenosis and the subsequent pressure gradient across the stenosis. Dogs with a pressure gradient of less than 50 mmHg are considered to have mild disease, those with a gradient of 50–80 mmHg are classified as having moderate disease, and severe stenosis would be that which creates a gradient greater than 80 mmHg. Dogs with mild or moderate SAS are considered to have a good prognosis and no treatment is recommended unless symptomatic. Dogs with severe SAS have been empirically treated with beta blockers, most commonly atenolol. However, in a recent retrospective review, beta blocker treatment did not influence survival in dogs with severe SAS (Eason et al., 2014).

Cardiac Arrhythmias

Beta-adrenergic receptor antagonists are categorized as Class II antiarrhythmics and are used for treating supraventricular and ventricular tachyarrhythmias. β-adrenergic receptor blockade increases the atrioventricular nodal refractory period and slows ventricular response rates in atrial flutter and fibrillation, and reduces ventricular ectopic beats, particularly those precipitated by catecholamines. The β-adrenergic receptor antagonist sotalol has antiarrhythmic effects involving ion channel blockade and prolongs the action potential and extends the refractory period (class III antiarrhythmic).

Ocular Disease

Timolol maleate is a nonselective β-adrenergic receptor antagonist that lowers intraocular pressure by decreasing aqueous humor production. In normal dogs and cats, topical application of timolol results in reduction of intraocular pressure in the treated eye and the contralateral eye, as well as miosis in the treated eye in cats and in the treated and contralateral eye in dogs (Wilkie and Latimer, 1991a, 1991b). Timolol maleate is available in a 0.25% and 0.5% solution and dosing is every 12 hours. In general, the 0.25% solution is recommended for small dogs and in cats due to the possibility of systemic absorption of the drug and systemic effects. Potential systemic side effects of topical timolol include bradycardia, cardiac arrhythmias, heart block (β_1-adrenergic receptor blockade), and pulmonary effects such as exacerbation of asthma and bronchospasm (β_2-adrenergic receptor blockade). Topical timolol should be avoided in patients with cardiac or pulmonary disease. Betaxolol is a β_1-selective receptor antagonist, which has been shown to significantly delay the onset of glaucoma in dogs with primary closed angle glaucoma (Miller et al., 2000).

Cholinergic Pharmacology: Autonomic Drugs

Rose M. McMurphy, Elizabeth G. Davis, Amy J. Rankin, Marjory A. Artzer, Barbara J. Lutjemeier, and Michael J. Kenney

The authors thank HR Adams for the original chapter upon which this is based.

Acetylcholine (ACh) is the primary neurotransmitter at autonomic ganglia, parasympathetic neuroeffector junctions, some sympathetic neuroeffector junctions, somatic neuromuscular junctions, the adrenal medulla (Figure 8.1 provides examples of each of these innervations), and certain regions of the central nervous system (CNS). In this chapter, drugs that influence postganglionic parasympathetic neuroeffector junctions and autonomic ganglia are examined.

Parasympathomimetic Agents

Cholinergic is used to describe nerve fibers that synthesize and release ACh without distinction as to anatomic site of action (Figure 8.2). Parasympathomimetic is used specifically to describe an ACh-like effect on effector cells innervated by postganglionic neurons of the parasympathetic nervous system (PSNS). The spectrum of responses to parasympathomimetic drugs is not entirely restricted to PSNS effects, and may include cholinergic actions throughout the body (Barnes and Hansel, 2004; Brown and Taylor, 2006; Westfall and Westfall, 2006).

Based on mechanism of action, drugs that produce parasympathomimetic effects can be divided into two major groups (Figure 8.3): direct-acting agents, which like ACh activate cholinergic receptors located on effector cells; and cholinesterase inhibitors, which allow endogenous ACh to accumulate and thereby intensify and prolong its action (Brown and Taylor, 2006). Similar compounds are also used as antiparasitics and insecticides, and anesthetics, areas fully described in later chapters of this text.

Cholinergic Receptors

Acetylcholine is the principal endogenous agonist at two primary types of cholinergic receptors, nicotinic and muscarinic. Nicotinic neural (NN) receptors associated with the autonomic nervous system (ANS) are present on postganglionic neurons in autonomic ganglia and mediate neurotransmission from preganglionic to postganglionic neurons in both the sympathetic nervous system (SNS) and the PSNS. NN receptors are also present on adrenal medullary chromaffin cells and mediate neurotransmission from preganglionic SNS neurons to adrenal medullary chromaffin cells. Nicotinic muscle (NM) receptors are involved in mediating signal transmission at the neuromuscular junction and are an essential component of the somatic nervous system. Nicotinic receptors are ligand-gated ion channels and contain five homologous subunits organized around a central pore (Stokes et al., 2015). Activation of these receptors initiates: a rapid increase in cellular permeability to selective cations (Na^+ and Ca^{2+}); cell membrane depolarization; and excitation of postganglionic ANS neurons, adrenal medullary chromaffin cells, or skeletal muscle fibers (Stokes et al., 2015).

Muscarinic receptors are located predominately at postsynaptic sites, such as the heart, gastrointestinal tract, glands, and urinary bladder, which are innervated by postganglionic parasympathetic nerves. Five subtypes of muscarinic receptors have been identified and many of the physiological functions associated with PSNS activation are mediated by muscarinic2 (M2) and muscarinic4 (M4) receptors. Muscarinic receptors are G protein-coupled receptors (GPCRs), and activation of these receptors may elicit an excitatory or inhibitory response (Calebiro et al., 2010; Jalink and Moolenaar, 2010; Ambrosio et al., 2011; Vischer et al., 2011; Latek et al., 2012; Duc et al., 2015).

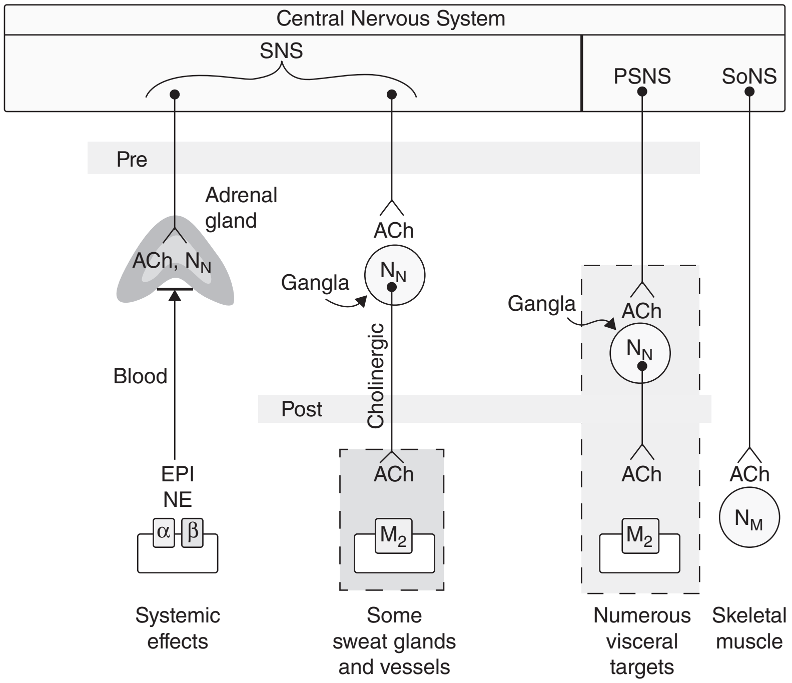

Figure 8.1 Schematic representation of the preganglionic and postganglionic anatomical relationships of nerves contained in the sympathetic nervous system (SNS) and the parasympathetic nervous system (PSNS). The anatomical substrate of somatic motor nerves (SoNS) is also shown. Only the primary neurotransmitters are shown. Acetylcholine (ACh) is the neurotransmitter released at sympathetic and parasympathetic ganglia and at most parasympathetic neuroeffector junctions. "Visceral targets" refers to cardiac muscle, glands, and bladder smooth muscle. Note that some sympathetic postganglionic fibers release ACh. The adrenal medulla, a modified sympathetic ganglion, is innervated by sympathetic preganglionic fibers and releases epinephrine and NE into the blood. ACh, acetylcholine; EPI, epinephrine; M, muscarinic receptors; NN, nicotinic receptors; NE, norepinephrine.

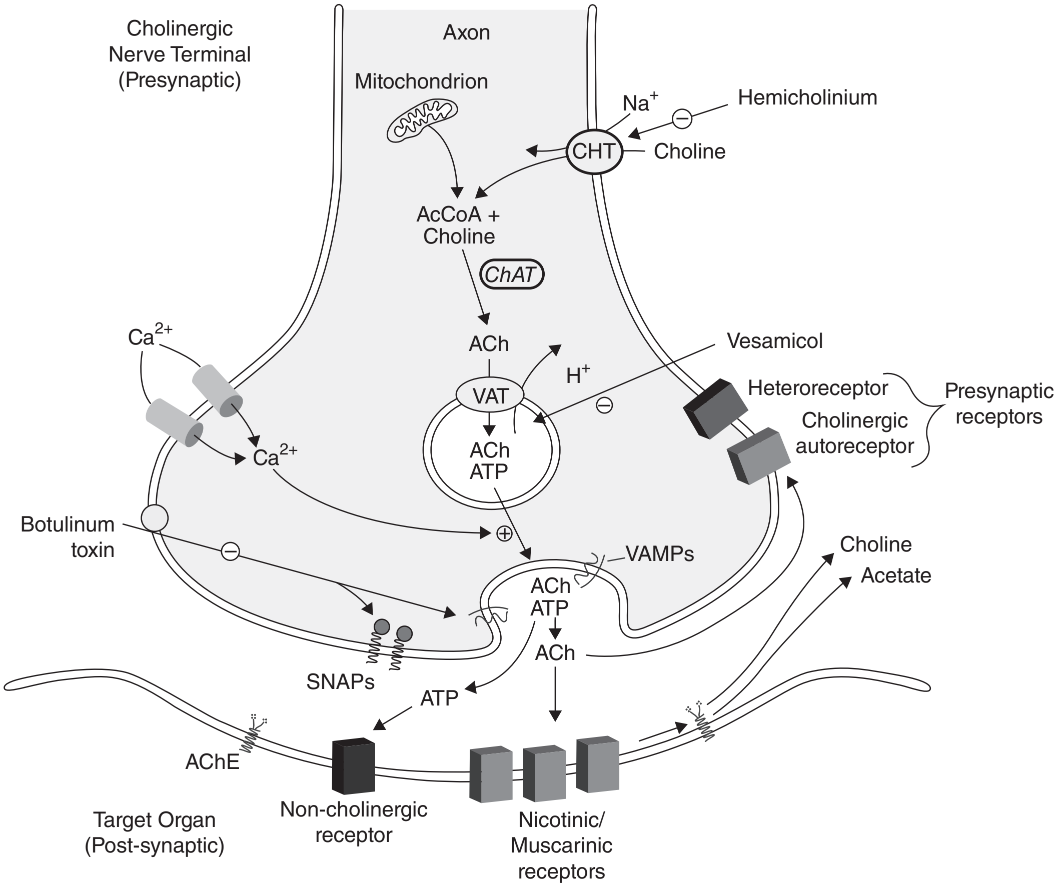

Figure 8.2 Schematic diagram depicting physiological processes at the site of a cholinergic nerve terminal innervating a target tissue. Processes have been described previously in Chapter 6. Cholinergic neurons synthesize and release ACh and this endogenous neurotransmitter binds to and activates nicotinic and muscarinic receptors. ACh, acetylcholine; AcCoA, acetyl-CoA; ChAT, choline acetyltransferase; CHT, choline transporter; SNAP, synaptosomal nerve-associated protein; VAT, vesicle-associated transporter; VAMP, vesicle-associated membrane protein.

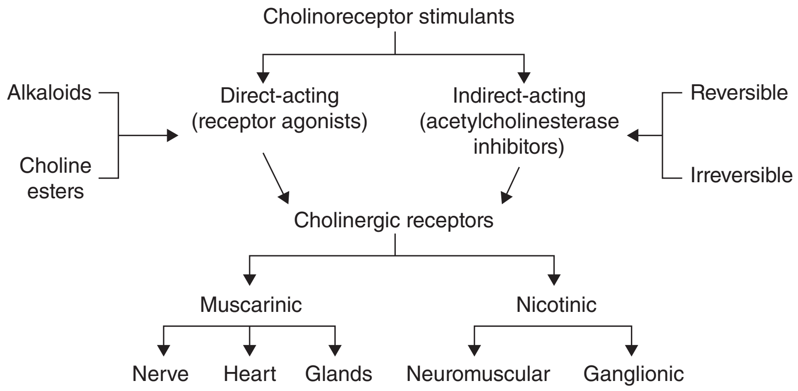
Figure 8.3 Schematic summarizing primary cholinergic receptor stimulants, muscarinic and nicotinic receptors, and target tissues.



Direct-acting Parasympathomimetic Agonists

General Characteristics

Direct-acting parasympathomimetic agonists consist of choline esters, including ACh and numerous synthetic esters, and cholinomimetic alkaloids. Methacholine, carbachol, and bethanecol are primary choline derivatives, whereas muscarine, pilocarpine, and arecoline are primary cholinomimetic alkaloids. Pharmacological effects of ACh and related choline esters and alkaloids are mediated by activation of cholinergic receptors located on cells innervated by cholinergic nerves and, in some cases, on cells that lack cholinergic innervation. Direct-acting agonists act directly on receptors and do not depend upon endogenous ACh for their effects. In general, the physiological responses of selected organs and effector tissues elicited by activation of efferent parasympathetic nerves, as well as direct-acting parasympathomimetic agonists, are similar (Table 8.1). However, the pharmacological characteristics of direct-acting parasympathomimetic agonists demonstrate nonuniform susceptibility to metabolism by cholinesterases, differential relative affinity for muscarinic and nicotinic receptors, and specificity in target organ effects (Table 8.2).

Structure–Activity Relationships

Direct-acting cholinergic agonists contain structural groupings that allow interaction of the agent with cholinergic receptors and result in similar membrane and cellular responses to those caused by ACh. Chemical structures of several choline esters and cholinomimetic alkaloids are shown in Figures 8.4 and 8.5.

Choline esters contain a quaternary nitrogen atom to which three methyl groups are attached. Except for some naturally occurring cholinomimetic alkaloids, a quaternary nitrogen moiety is usually required for a direct potent action on cholinergic receptors. The quaternary nitrogen group carries a positive charge and this cationic group electrostatically binds with a negatively charged (anionic) site of the cholinergic receptor.

Receptive macromolecules (i.e., cholinergic receptors and cholinesterases) that recognize and bind ACh have, in addition to the anionic site, a region that combines

Table 8.1 Effects of direct-acting cholinergic receptor stimulants

Organ	Tissue	Response

with the ester component of ACh (Hucho et al., 1991). In cholinesterase, this region is called the esteratic site and its combination with the carboxyl group results in hydrolysis of the ester. Hydrolysis of ACh does not occur upon its interaction with a receptor, however, and the ester-attracting region of the receptor is called the esterophilic site (Inestrosa and Perelman, 1990; Taylor, 1991, 2006a; Massoulie et al., 1993). ACh is structurally arranged so that it combines with the esterophilic and anionic sites of both nicotinic and muscarinic receptors and acetylcholinesterases (Hucho et al., 1991).

ACh is the prototypical cholinergic agent and activates both nicotinic and muscarinic receptors. Acetyl-β-methylcholine (methacholine) is identical in structure to ACh except for the substitution of a methyl group on the β-carbon atom of the choline group. This structural change yields a compound that is primarily a muscarinic receptor agonist lacking significant nicotinic effects when given in usual dosages. Further, it is more active on the cardiovascular system than on the GI tract. Duration of action of methacholine is considerably longer than that of ACh.

Carbachol and bethanechol each have a carbamyl group substituted for the acetic moiety of ACh, and bethanechol also has a β-methyl group. Both of these agents are almost completely resistant to inactivation by the cholinesterases. Their duration of action is therefore considerably longer than that of ACh. Carbachol is active at both muscarinic and nicotinic receptor sites, whereas bethanechol is primarily a muscarinic agonist. Unlike methacholine, both these drugs are somewhat more active on smooth muscles of the GI tract and urinary bladder than on cardiovascular function. Pharmacological characteristics of these choline esters are presented in Table 8.2.

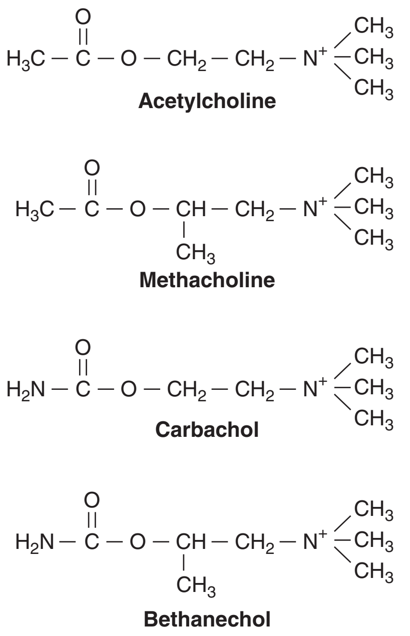

Figure 8.4 Molecular structures of primary choline esters.

Acetylcholine: Prototypical Cholinergic Agonist

Pharmacological Mechanisms and Effects

ACh is the prototypical cholinergic agonist and therefore provides a foundation for understanding the pharmacological effects of other cholinomimetic drugs. The

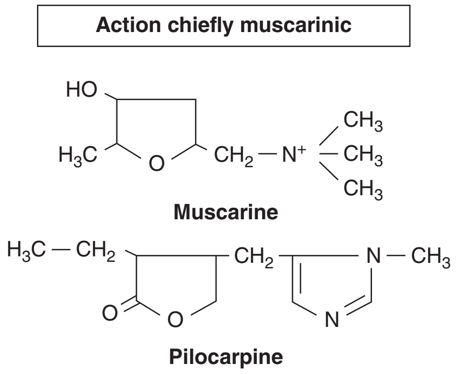

Figure 8.5 Molecular structures of several cholinomimetic alkaloids.

biosynthesis, neuronal release, cellular activities, and inactivation of endogenous ACh were discussed in Chapter 6. Although an essential ANS neurotransmitter, ACh is not used therapeutically for at least two reasons. First, muscarinic and nicotinic receptors are located at numerous tissue sites and therefore no selective therapeutic response to ACh can be achieved. Second, its duration of action is quite brief because it is rapidly inactivated by the cholinesterases. Several derivatives of ACh are more resistant to hydrolysis by cholinesterase and have a somewhat greater selectivity in their sites of action (Table 8.2).

Since ACh is a mixed nicotinic–muscarinic agonist, different physiological response profiles can be produced by administration of this agent, depending upon the relative dominance of muscarinic (parasympathomimetic) or nicotinic actions. These effects can be differentiated by use of small and large doses of ACh and by using selective cholinergic blocking drugs. In general, parasympathomimetic effects dominate with small doses, whereas with large doses nicotinic effects can be elicited. Use of cholinergic blocking drugs and small and large doses of ACh to differentiate muscarinic and nicotinic effects of ACh is shown in Figure 8.4. This figure is discussed in more detail in the following section regarding cardiovascular effects mediated by ACh administration.

Target Organ Effects of ACh

Cardiovascular: Intravenous (IV) administration of small amounts of ACh (5– 10 μg/kg) induces a brief but rapid fall in systolic and diastolic blood pressures, due to a decrease in peripheral resistance resulting from dilation of blood vessels. Most blood vessels receive little or no parasympathetic innervation, and muscarinic receptors located at these sites are noninnervated. Muscarinic receptors mediating dilation of blood vessels are located on the endothelium rather than on the smooth muscle, and the smooth muscle relaxation in response to ACh administration involves the production and release of nitric oxide (Furchgott and Zawadzki, 1980; Lowenstein et al., 1994).

Somewhat larger doses of ACh (10–30 μg/kg) produce pronounced muscarinic effects; therefore, marked reductions in peripheral resistance, heart rate, and blood pressure are observed. Atrial myocardial cells contain muscarinic receptors associated with vagal fibers, and activation of these receptors by ACh produces negative chronotropic and inotropic effects. Generally, the chronotropic effects predominate. In addition to its pronounced slowing effect on heart rate, ACh exerts important effects on impulse conduction.

With high doses (50–100 μg/kg) muscarinic effects of ACh on postganglionic effector cells are accentuated. Profound hypotensive and bradycardic responses are observed. Large doses of ACh produce, in addition to muscarinic (i.e., parasympathomimetic) effects, stimulation of the nicotinic receptors in autonomic ganglia (both parasympathetic and sympathetic) and the adrenal medulla. These effects are particularly evident when the muscarinic receptors of the parasympathetic neuroeffector junctions are blocked by atropine (nonselective muscarinic receptor antagonist). Under these circumstances large doses of ACh stimulate nicotinic receptors of both sympathetic and parasympathetic ganglia. However, because the muscarinic receptors of the parasympathetic neuroeffector junctions are blocked by atropine, the ACh released from postganglionic parasympathetic nerves does not bind to and activate the target organ muscarinic receptors. Under this condition, sympathomimetic responses will be evident, including increased arterial blood pressure, tachycardia, and other typical sympathetic-mediated effects. These effects can be blocked by use of appropriate adrenergic blocking drugs or by use of a ganglionic blocking agent (Figure 8.6).

Nonvascular smooth muscle: ACh stimulates smooth muscle of the urinary bladder and uterus to contract (Chapple et al., 2002). Bronchiolar smooth muscle is also contracted by ACh, resulting in decreased airway diameter (Barnes and Hansel, 2004; Fisher et al., 2004). The smooth muscle effects of ACh are due to muscarinic receptor activation.

Gastrointestinal system: Gastrointestinal motility and secretions are enhanced by ACh in a manner similar to that mediated by stimulation of the PSNS innervation to the gastrointestinal system. These effects may be difficult to detect with small doses because duration of action of ACh is brief owing to rapid destruction by cholinesterase. Larger doses markedly increase secretions and peristaltic movements of the GI tract.

Central nervous system: ACh does not readily cross the blood–brain barrier, therefore CNS effects are not observed when usual dosages are administered. However, intraarterial ACh injection into cerebral arteries or the direct application of ACh into the CNS produces central neural excitation. Both muscarinic and nicotinic receptors are present in the CNS (Krnjevic, 2004).

Adrenal medulla: The adrenal medulla is functionally analogous to autonomic ganglia, and nicotinic receptors located on adrenal medullary chromaffin cells are innervated by preganglionic sympathetic nerve fibers. These receptors are stimulated by ACh to cause release of epinephrine and norepinephrine from chromaffin cells into the circulation. This effect contributes to the overall nicotinic-mediated sympathomimetic effect evoked by large doses of ACh in the presence of muscarinic receptor blockade.

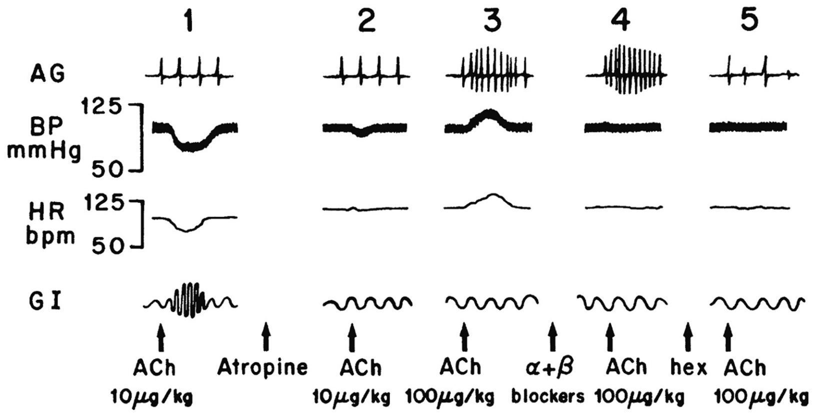

Figure 8.6 Muscarinic and nicotinic effects of acetylcholine (ACh) on blood pressure, heart rate, intestinal motility, and autonomic ganglionic action potentials in an anesthetized dog. Schematic reproductions: (1) A small dose of ACh (10 mg/kg) administered intravenously causes hypotension, bradycardia, and intestinal contractions caused by direct stimulation of muscarinic receptors of blood vessels, heart, and intestinal smooth muscle, respectively. These effects are brief because of rapid destruction of ACh by cholinesterase. (2) Atropine blocks the muscarinic receptors and thereby prevents the effects seen in (1). (3) Large doses of ACh (100 mg/kg) stimulate, in addition to muscarinic receptors, nicotinic receptors of parasympathetic and sympathetic ganglionic neurons, causing an increase in frequency and amplitude of ganglionic action potentials. Although all autonomic ganglia are activated, impulses arising from parasympathetic ganglia do not reach their effector cells because of blockade of parasympathetic postganglionic neuroeffector junctions by atropine. Sympathomimetic responses (pressor effect and tachycardia) result. (4) Impulses arising from sympathetic ganglia are prevented from reaching their effector cells by adrenergic blocking drugs; however, ganglionic nicotinic receptors are still activated by ACh. (5) Hexamethonium (hex) blocks nicotinic receptors of ganglia and thereby inhibits the nicotinic ganglionic stimulating effect of ACh and reduces ganglionic action potentials. AG, action potentials of autonomic ganglionic neuron; BP, systemic blood pressure; HR, heart rate; GI, intestinal peristaltic waves.

Choline Esters: Methacholine, Carbachol, and Bethanecol

Pharmacological Mechanisms and Effects

The pharmacological effects of methacholine, carbachol, and bethanecol are similar to the parasympathomimetic effects produced by ACh administration, and therefore are consistent with the physiological responses evoked by the activation of postganglionic parasympathetic nerves. However, the physiological response profiles produced by different choline esters are not identical, and vary in relative selectivity for one organ system or another (Table 8.2).

Methacholine is a synthetic choline ester that produces cardiovascular effects similar to those produced by ACh, but has a longer duration of action and its primary agonistic activity is at muscarinic receptors. Carbachol is active at both muscarinic and nicotinic receptors, and nicotinic neural receptors are particularly sensitive to carbachol. The pharmacological scope of activity of bethanecol is similar to that of methacholine and carbachol. Unlike carbachol, however, bethanecol is primarily a muscarinic agonist and has little stimulant effects on nicotinic receptors.

Target Organ Effects

Cardiovascular: Methacholine is more active on the cardiovascular system than on the GI or urinary tracts. The opposite selectivity is seen with carbachol and bethanechol. Intravenous administration of methacholine, like ACh, produces a depressor response and slowing of heart rate caused by activation of muscarinic receptors located on blood vessels and in the heart. Cardiac rhythm is altered by methacholine, and the atrioventricular node is particularly sensitive to this agent. Carbachol evokes blood pressure changes similar to, but less pronounced, than those produced by methacholine, whereas bethanechol administration produces considerably less effects on cardiovascular function.

Gastrointestinal system: Carbachol and bethanecol are relatively more active on the gastrointestinal and urinary tracts than on the cardiovascular system. Methacholine administration affects gastrointestinal function, but only in large doses. Carbachol is a potent GI stimulant and increases salivation and peristaltic movements of the gastrointestinal system.

Nonvascular smooth muscle: Carbachol causes contraction of bronchiolar smooth muscle, resulting in a decreased airway. The urinary bladder is contracted by carbachol and bethanechol. Effects of carbachol and bethanechol on smooth muscle are mediated by activation of muscarinic receptors.

Clinical Uses

There are few clinical indications for the use of these cholinergic agonists in veterinary medicine. Bethanechol has been used to promote bladder contraction in paraplegic dogs and cats with the goal to prevent over distension and detrusor muscle atony (Schubert, 2015). The use of bethanechol to promote detrusor muscle contraction for treatment of detrusor sphincter dysynergia, in conjunction with diazepam and prazosin to decrease urethral sphincter tone, has been reported (Jeyraja et al., 2010; Chandrasekar et al., 2013). The only clinical use for carbachol is as the ophthalmic solution Miostat®, which is administered at the end of cataract surgery to cause miosis.

Cholinomimetic Alkaloids: Pilocarpine, Muscarine, and Arecoline

Pharmacological Mechanisms and Effects

Pilocarpine, arecoline, and muscarine are plant alkaloids that are rather selective parasympathomimetic agents (i.e., their cholinomimetic activity is exerted primarily at muscarinic sites with minimal nicotinic effects). These cholinomimetic alkaloids evoke their parasympathomimetic effects by direct activation of muscarinic receptors.

Target Organ Effects

Pilocarpine is particularly effective in stimulating flow of secretions from exocrine glands, including; salivary, mucous, gastric, and digestive pancreatic secretions. As with ACh, it causes contraction of GI smooth muscle, thereby increasing smooth muscle tone and peristaltic activity. Of considerable importance, pilocarpine has a potent constrictor effect on the pupil.

Arecoline activates muscarinic receptors located at numerous targets including; glands, smooth muscles, and myocardium, and produces the usual parasympathomimetic effects. It is similar to pilocarpine in scope of activity.

Clinical Uses

Pilocarpine hydrochloride is available as a 1%, 2%, and 4% ophthalmic solution (see Chapter 49). Topical pilocarpine causes miosis and lowers the intraocular pressure. Although pilocarpine has been recommended historically to treat glaucoma, the topical irritation caused by this medication can be severe, making the medication poorly tolerated by most patients. Newer antiglaucoma medications are generally less irritating, and thus are recommended more commonly. Pilocarpine can be used to treat cases of neurogenic keratoconjunctivitis sicca in dogs. In order for pilocarpine to be effective there must be some normal functioning lacrimal tissue, and it is unlikely to increase tear production in cases of absolute keratoconujunctivitis sicca (Giuliano, 2013). Oral administration of pilocarpine should be performed with caution in small patients due to the increased risk of toxic systemic effects and death. Alternatively, a dilute pilocarpine solution (0.125% or 0.25%) can be applied directly to the eye to stimulate tear production. Pilocarpine can be used for pharmacological testing and neuroanatomic localization of mydriasis caused by dysfunction of the parasympathic nervous system. Ocular application of dilute pilocarpine solution (0.05%) in dogs with dysautonomia will cause rapid constriction of the pupil in less than 45 minutes compared to unaffected animals (O'Brien and Johnson, 2002). The rapid miosis is secondary to the degeneration of the postganglionic neurons, which leads to hypersensitivity of the denervated muscle to cholinergic drugs. In dogs with mydriasis due to a lack of parasympathic innervation of the iris sphincter muscle (internal ophthalmoplegia), the sphincter muscle will be hypersensitive to topical application of a dilute (0.1%) pilocarpine solution.

Cholinesterase Inhibitors

Pharmacological Mechanisms and Effects

Cholinesterase inhibitors (anticholinesterase agents) inactivate or inhibit acetylcholinesterase (AChE) and pseudocholinesterase, increasing the level of synaptic ACh, and intensifying the activity of endogenous ACh. Because cholinesterase inhibitors enhance the actions of endogenous ACh at all cholinergic receptors, their scope of activity is not limited to parasympathomimetic effects but can include cholinomimetic actions throughout the body (Taylor, 2006b). Effects of cholinesterase inhibitors can be reliably predicted by considering the anatomic location of cholinergic nerves and the respective physiological processes they modulate at target cells and tissues. Parasympathomimetic (muscarinic) effects of these agents are equivalent to the effects associated with activation of postganglionic parasympathomimetic nerves. Cholinesterase inhibitors also cause intensification of ACh activity at nicotinic sites.

Physostigmine, neostigmine, and edrophonium are examples of anticholinesterase drugs that produce a reversible inhibition of cholinesterase, whereas organophosphate compounds produce an irreversible inhibition. Although there is considerable distinction between these two groups of anticholinesterases, their pharmacological effects are similar because of a common mechanism of action. The pharmacological effects of cholinesterase inhibitors can be explained almost entirely by their characteristic inhibitory action on AChE. This results in decreased hydrolysis of neuronally released ACh and intensification of its action at cholinergic receptors. Neostigmine and some other quaternary nitrogen anticholinesterase agents exert some direct effects (either agonistic or antagonistic) on cholinergic receptors in addition to inhibition of cholinesterase.

Structure–Activity Relationships

The enzymatic interactions of AChE, ACh, and cholinesterase inhibitors can be summarized as follows (Inestrosa and Perelman, 1990; Taylor, 1991, 2006a; Massoulie et al., 1993). AChE contains two active sites that recognize specific parts of the ACh molecule: (i) an anionic (negatively charged) region where electrostatic binding occurs with the cationic nitrogen of the choline moiety; and (ii) an esteratic site where the carboxyl portion of the acetyl ester binds to it by covalent bonding. After ACh–AChE interaction occurs, the choline portion is split off, leaving the acetylated esteratic site. Acetic acid is rapidly formed as water reacts with the acetyl group, and the enzyme is thereby reactivated (Wilson, 1954).

Neostigmine, physostigmine, and other carbamate derivatives interact with the anionic and esteratic sites of the enzyme, thereby preventing ACh from affixing to the enzyme. Neostigmine and physostigmine are believed to be hydrolyzed in a manner similar to but much slower than that of ACh (Wilson et al., 1960). Although the rate of combination of inhibitor with AChE is only a few times slower than the analogous combination of ACh with the enzyme, the rate of hydrolysis is much faster for ACh. Therefore, neostigmine and related drugs are reversible cholinesterase inhibitors as a result of their actions as competitive substrates that are hydrolyzed at a much slower rate than the endogenous substrate ACh (Taylor, 1991, 2006a; Massoulie et al., 1993).

Edrophonium is a simple alcohol bearing one quaternary ammonium group. Edrophonium binds to the anionic site of cholinesterase by electrostatic attachment and at the esteratic site by hydrogen bonding. The action of edrophonium is brief because a covalent bond is not formed (Keegan, 2015).

Organophosphate compounds interact with AChE at the esteratic site and form an extremely stable enzyme–inhibitor complex that does not undergo significant spontaneous disassociation. The esteratic site is persistently phosphorylated, and recovery of cholinesterase activity is dependent upon de novo synthesis of new enzyme.

Reversible Inhibitors: Physostigmine, Neostigmine, Edrophonium, Pyridostigmine

Pharmacological Mechanisms and Target Organ Effects

As stated previously, these drugs produce their effects by combining with cholinesterase and thereby preventing the enzyme from hydrolyzing ACh. In general, the physiological responses produced by these drugs are similar to direct-acting parasympathomimetic agents, and therefore are consistent with the physiological responses evoked by stimulation of postganglionic parasympathetic nerves.

Digestive tract: Physostigmine and neostigmine cause contraction of smooth muscle, thereby increasing motility and peristaltic movements of the gut. Frequency and strength of peristaltic waves are increased, and movement of intestinal contents is accelerated.

Eyes: Physostigmine causes pupillary constriction when applied locally to the eye or when injected for systemic effect.

Skeletal muscle: Besides its major action of inactivating AChE at the somatic myoneural junction, neostigmine is believed to directly stimulate nicotinic receptors of skeletal muscle fibers. The skeletal muscle effects of neostigmine are relatively more pronounced at low doses than the smooth muscle effects of this agent. Twitching of skeletal muscles may be observed when a large dose of physostigmine or neostigmine is injected.

Other effects: A therapeutic dose of physostigmine or neostigmine does not produce pronounced effects on cardiovascular function. Effects of higher doses are complicated by concurrent ganglionic stimulation and muscarinic effects on the heart and blood vessels. Usually, hypotension and a bradycardia are produced. Smooth muscle of the bladder is cholinergically innervated and therefore is contracted by cholinesterase inhibitors. Bronchiolar smooth muscle is also contracted by these agents.

Clinical Uses

Physostigmine, pyridostigmine, neostigmine, and edrophonium can be used to reverse the effects of nondepolarizing neuromuscular blocking drugs in voluntary muscles. AChE inhibitors are used in the therapy of dogs but rarely cats, with myasthenia gravis (MG). Additionally, intravenous edrophonium is sometimes used as an initial screening test for dogs with suspected MG. MG results from either a rare congenital absence of nicotinic receptors at the neuromuscular junction or as an acquired autoimmune diseases resulting in destruction and deficiency of these AChRs. The edrophonium chloride response test is used to make a presumptive diagnosis. Edrophonium is used because of its ultrashort action. A positive response is defined as a temporary increase in muscle strength after administration of the drug (Khorzad et al., 2011). This is not a definitive test and both false-positive and false-negative results are possible. A definitive diagnosis of MG is made by documentation of autoantibodies against muscle AChRs by immunoprecipitation radioimmunoassay. Oral AChE inhibitors are used in the therapy for MG.

Unlike humans, spontaneous remission of acquired MG in dogs is likely (Shelton and Linstrom, 2001) and treatment is aimed at improving muscle strength while titrating the dose to minimize other cholinergic side effects. Pyridostigmine bromide and neostigmine bromide are the most commonly used AChE inhibitors for MG. Pyridostigmine is preferred because of its longer duration of action and lower potential for adverse gastrointestinal effects. In dogs with MG, pyridostigmine bromide is administered at 0.5–3.0 mg/kg orally two or three times daily (Khorzad et al., 2011). Adverse effects are related to the muscarinic effects of excess ACh and include increased gastrointestinal motility, diarrhea, salivation, and bradycardia.

Toxicology

Large doses of physostigmine first stimulate and then depress the CNS; small to moderate doses have little effect, whereas massive doses can produce convulsions. Neostigmine does not cross the blood–brain barrier to an appreciable extent. Toxic doses of these agents produce marked skeletal muscle weakness, nausea, vomiting, colic, and diarrhea. The pupil is markedly constricted and fixed. Dyspnea is characteristically seen from constriction of the bronchiolar musculature. Bradycardia and lowered blood pressure are also characteristic signs. Respiratory paralysis caused by depolarization block of the neuromuscular junction and compounded by excess bronchiolar secretions is the usual cause of death. Atropine is the most effective pharmacological antagonist for physostigmine or neostigmine toxicity.

Organophosphorus Compounds

Organophosphates irreversibly phosphorylate the esteratic site of both AChE and the nonspecific or pseudocholinesterase throughout the body. Endogenous ACh is not inactivated, and the resulting effects are due to the excessive preservation and accumulation of endogenous ACh (Gutmann and Besser, 1990; Taylor, 1991, 2006a). Organophosphate poisoning produces diffuse cholinomimetic effects: profuse salivation, vomiting, defecation, hypermotility of the GI tract, urination, bradycardia, hypotension, severe bronchoconstriction, and excess bronchial secretions. These signs reflect excess activation of muscarinic receptors of postganglionic parasympathetic neuroeffector junctions with typical parasympathomimetic actions.

In addition to the muscarinic effects, organophosphates produce skeletal muscle fasciculations, twitching, and, subsequently, muscle paralysis occurs. These effects are due to persistent excessive stimulation of the nicotinic receptors of skeletal neuromuscular junctions, resulting in the depolarizing type of striated muscle paralysis (Gutmann and Besser, 1990). Convulsions and frequently death are seen in organophosphate poisoning, caused by penetration of the agent into the CNS and subsequent intensification of the activity of ACh at CNS sites (Gutmann and Besser, 1990).

Atropine is a competitive antagonist to ACh and therefore administration of this muscarinic receptor antagonist can reduce the severity of the parasympathomimetic effects produced by organophosphates, and can also increase the quantity of organophosphate required to produce death. An atropine test can be completed if signs of organophosphate poisoning are present (Wismer, 2012).

Although phosphorylation of the esteratic site of cholinesterase by organophosphates yields a normally irreversible complex, certain compounds cause a disassociation of the enzyme link. Pralidoxime (pyridine-2-aldoxime-methiodide, 2-PAM) was synthesized based on structural requirements postulated by Wilson (1958) to be necessary for a selective antidote to the organophosphate–cholinesterase interaction. This compound causes an effective removal of the phosphate group from the enzyme, so the enzyme is reactivated. This oxime compound is an adjunct to atropine therapy in treating organophosphate poisoning.

Animals previously exposed to toxic doses of organophosphates experience considerable improvement after treatment with 2-PAM. Since 2-PAM significantly reverses the combination of organophosphate with cholinesterase, the reactivated enzyme can then perform its normal function. The phosphorylated enzyme complex tends to age with time and to become resistant to reactivation by oximes.

Muscarinic Receptor Antagonists

Muscarinic receptor antagonists block the effects of ACh and related cholinergic receptor agonists from binding to and activating muscarinic receptors; therefore they are termed antimuscarinic agents or muscarinic receptor antagonists. Both naturally occurring antimuscarinic compounds and synthetic antimuscarinic compounds are available for use. Atropine, the prototypical muscarinic blocking agent, is an alkaloid extracted from *Atropa belladonna* (deadly nightshade) and *Datura stramonium* (jimsonweed), whereas scopolamine (hyoscine) is found in *Hyoscyamus niger* (henbane). There are numerous synthetic drugs with antimuscarinic effects, including propantheline, glycopyrrolate, tropicamide, and butylscopolamine. The following sections focus primarily on atropine because it is the prototype muscarinic receptor-blocking agent.

Mechanism of Action

Muscarinic receptor antagonists interact with muscarinic receptors of effector cells and, by occupying these sites, prevent ACh from binding to the receptor. Physiological responses to parasympathetic nerve impulses are thereby attenuated. Blockade of muscarinic receptors of smooth muscle, cardiac muscle, and glands by atropine-like drugs involves a competitive antagonism and large doses of ACh or other cholinomimetic drugs (e.g., carbachol, cholinesterase inhibitors) can overcome inhibitory effects of atropine at these sites.

Antimuscarinic drugs, such as atropine and scopolamine, are considered nonspecific for different muscarinic receptor subtypes; however, the physiological effects of the drugs are somewhat dose and drug dependent. For example, salivary and cholinergic sweat glands are quite susceptible to small doses of atropine, whereas somewhat larger doses are required for blocking the effect of the vagus nerve on the heart. GI and urinary tract smooth muscles are less sensitive to atropine, and even larger dosages are required to inhibit gastric secretion. Except for effects on salivation and cholinergic sweating, it is difficult to achieve a selective action on targeted structures without concurrently inducing side effects on other, more susceptible sites. Net pharmacological effects of antimuscarinic drugs in a particular organ are influenced by the relative dominance of parasympathetic or sympathetic tone in that structure.

Pharmacological Effects

Cardiovascular system: An increase in heart rate and intranodal conduction velocity are the predominant effects of therapeutic doses of atropine. However, a dose-dependent decrease of heart rate and development of a second-degree atrioventricular block after treatment of bradycardia with atropine can occur. The effect of atropine on heart rate and the potential for subsequent tachycardia is dependent in part upon the degree of vagal tone. Because atropine blocks transmission of vagal impulses to the heart, animals with a preexisting high vagal tone would show a relatively greater tachycardia than those with low vagal tone.

Cardiac output may increase with atropine secondary to the increase in heart rate. Arterial blood pressure either remains unchanged or increases slightly as a result of the increased cardiac output. In animals exposed to exogenous ACh or other cholinomimetics (e.g., cholinesterase inhibitors), atropine can cause a relative increase in blood pressure, because muscarinic effects of the agonists will be blocked. Because atropine blocks the cardiac vagus, it markedly reduces or abolishes cardiac inhibitory effects of drugs acting through a vagal mechanism and will attenuate vagal-mediated reflex responses. Accordingly, the pressor effects of epinephrine and norepinephrine are accentuated in atropinized animals by blockade of the cardiac limb of vagal–baroreceptor reflexes.

Gastrointestinal system: Atropine causes relaxation of GI smooth muscle by inhibiting contractile effects of cholinergic nerve impulses. Thus, atropine and related drugs can be helpful in treatment of intestinal spasm and hypermotility. Inhibition of smooth muscle motility extends from stomach to colon, although the degree of blockade may not be uniform. Secretions of the GI tract are also blocked by atropine. Salivation is reduced quite markedly. Similarly, secretions of intestinal mucosa are inhibited; however, gastric secretions are reduced only with exceedingly high doses that also block virtually all other muscarinic sites.

Bronchioles: Cholinergic innervation to the bronchioles modulates secretion of mucus and contraction of bronchiolar smooth muscle via activation of muscarinic receptors. Atropine and other drugs of the belladonna group block effects of cholinergic impulses and thereby decrease secretions and increase luminal diameter of the bronchioles. The dilator action of atropine is valuable in counteracting constriction of bronchioles following overdosage of a parasympathomimetic drug.

Ocular effects: Atropine blocks the cholinergically innervated sphincter muscle of the iris and the ciliary muscle, resulting in mydriasis and cycloplegia after topical or systemic administration. Because atropine blocks cholinergic effects, adrenergic nerve impulses dominate and the pupil actively dilates. Atropine is contraindicated in the presence of increased intraocular pressure from glaucoma because the drainage system of the anterior chamber of the eye is impeded during mydriasis.

Urinary tract: Atropine relaxes smooth muscle of the urinary tract. The spasmolytic effect on the ureters may be of some benefit in treatment of renal colic. Atropine tends to cause urine retention because it inhibits smooth muscle tone.

Sweat glands: Atropine has a definite anhydrotic action in species such as humans, who have a cholinergic mechanism in control of sweat secretion, and a large dose may cause a hyperpyrexic response. Atropine does not directly affect sweating in species that have adrenergic mechanisms in control of sweating (e.g., equines) and has minimal effect in species that do not use cholinergic sweating as an important component of thermoregulation.

Central nervous system: Therapeutic doses of atropine produce minimal effects on the CNS (Fisher et al., 2004). Excessive doses may cause hallucinations and disorientation in humans and mania and excitement in domestic animals. Excessive motor activity followed by depression and coma is the usual sequence of events. Scopolamine has a slight sedative effect; when combined with morphine it produces analgesia and amnesia (referred to as "twilight sleep") in human patients. These effects of scopolamine usually are not detectable in domestic animals.

Clinical Uses

Muscarinic receptor antagonists can be used as antispasmodics or spasmolytics to control smooth muscle spasm. Antispasmodics can be used to decrease or abolish GI hypermotility and depress hypertonicity of the uterus, urinary bladder, ureter, bile duct, and bronchioles. Antimuscarinic drugs are not as effective as epinephrine or other adrenergic amines in dilating the bronchioles, but atropine is effective in antagonizing excessive cholinergic stimulation at these sites.

Systemically administered atropine is used predominantly to treat bradyarrhythmias that are associated with significant effects on cardiac output and/or systemic blood pressure. Given that the duration of effect on heart rate is approximately 30–60 minutes, this limits the use of atropine to initial or emergency treatment of bradyarrhythmias, or, more frequently, as a treatment for bradycardia that is induced by other drugs such as mu agonist opioids or acetylcholinesterase inhibitors. The routine use of anticholingergic drugs as anesthetic premedicants is no longer recommended, and treatment of bradycardia associated with drugs that markedly increase vascular resistance, such as dexmedetomidine may be contraindicated. Atropine may be administered as a diagnostic test to determine the responsiveness of a bradyarrhythmia to an anticholinergic drug.

Atropine is used to facilitate ophthalmoscopic examination of internal ocular structures and also for treatment of various ocular disorders. Atropine sulfate is available as a 1% ophthalmic solution and ointment and is a potent mydriatic and cycloplegic. Atropine is used commonly in the treatment of iridocyclitis in veterinary medicine because of its long duration of action. In dogs, the peak onset of mydriasis after application of 1% atropine solution is within 1 hour, and the mydriasis lasts for 96–120 hours (Rubin and Wolfes, 1962). Patients with dark irides may have a delayed onset and longer duration of atropine due to binding of atropine by the melanin in the irides, where it is slowly released from the pigment onto the muscarinic receptors (Salazar and Patil, 1976). A common side effect associated with the use of topical atropine is excessive salivation and vomiting, which is most likely due the bitter taste of the drug. After topical application, a portion of the solution will enter the nasolacrimal duct and may be ingested. This side effect is more likely to occur with use of the solution compared to the ointment formulation. Atropine can cause an increase in intraocular pressure and can decrease tear production, therefore it should be avoided in patients with glaucoma or keratoconjunctivitis sicca.

Diagnostic ophthalmoscopy is more frequently facilitated by topical tropicamide. Tropicamide is available as a 0.5% and 1% solution. The rapid onset and short duration of action make it an ideal drug for diagnostic ophthalmoscopy. Tropicamide has less cycloplegic effects than atropine, and is not commonly used to treat iridocyclitis.

Glycopyrrolate

The antimuscarinic effects of this synthetic muscarinic receptor antagonist are similar to atropine. It is often considered that glycopyrrolate may be associated with a lower risk of marked tachyarrhymias when compared to atropine. While clinical experience would suggest this is the case in veterinary patients, there is little research data to support this (Lemke, 2001). In dogs this compound effectively diminishes the volume and acidity of gastric secretions and reduces intestinal motility; it also reduces and controls excessive secretions of the respiratory tract. Similar control of respiratory secretions by glycopyrrolate has been reported in cats, and its duration of action exceeds that of atropine. Also, because of its more polar nitrogen moiety, glycopyrrolate penetrates the blood–brain barrier less effectively than atropine, with less propensity for unwanted CNS side effects.

N-butylscopolamine bromide

N-butylscopolamine bromide (NBB) is a quaternary ammonium that serves as a peripherally acting antimuscarinic, anticholinergic agent similar in action to atropine, and is approved in the United States for use in horses that demonstrate colic signs resulting from gas, spasms, or mild impactions. The efficacy of NBB for the treatment of spasmodic colic was based on a multicentered field study of naturally occurring simple colic in horses (Roelvink et al., 1991).

The elimination half-life of NBB in plasma is approximately 6 hours. The pharmacological effects produced by NBB are consistent with those of other anticholinergic drugs. In a study of the hemodynamic parameters, NBB decreased right atrial pressure, while cardiac output was maintained. The hemodynamic changes were similar to those reported following the administration of low doses of other anticholinergic agents such as atropine.

Recent work has focused on the potential utility of NBB administration for the treatment of marked airway obstruction that may occur with conditions of airway inflammation such as recurrent airway obstruction or heaves. Current evidence provides support for the use of NBB as an immediate bronchodilator (Couetil et al., 2012). Although tachycardia and reduced gastrointestinal motility are valid considerations, based on the short duration of activity and evidence to support improved ventilator function it is considered an appropriate therapeutic option when managing equine patients with severe airway obstruction. Additional evidence to support the use of NBB in horses suffering from airway obstruction is supported by a cross-over investigation in recurrent airway obstruction affected horses where atropine and NBB provided similar bronchodilatory effects, yet the systemic effects such as pupillary dilation and one horse developing colic signs were only observed following atropine administration (de Lagarde et al., 2014). From this study it was concluded that NBB bromide was associated with fewer systemic side effects and is therefore a preferred treatment for reversible airway obstruction in horses. See Chapter 48 for further discussion.

Methantheline, Propantheline, and Methylatropine

These drugs are quaternary amines used primarily as smooth muscle relaxants. Because of the charged quaternary group, these compounds do not cross the blood–brain barrier to an appreciable extent. Accordingly, they are considerably less effective than atropine as antagonists to organophosphates, since the CNS effects of the latter agents would not be blocked. In addition to muscarinic blocking effects, these drugs act as autonomic ganglionic blockers, which most likely contributes to their antispasmodic effect on GI smooth muscle. Propantheline has been used in dogs with myasthenia gravis that develop significant muscarinic side effects in response to the administration of pyridostigmine.

Autonomic Ganglionic Blocking Drugs

Following Langley's investigations in 1889, it was known that small doses of nicotine stimulate autonomic ganglion cells, and larger doses block the transmitter function of ACh at these same sites. Therefore, the cholinergic receptors located at autonomic ganglia, primarily on postganglionic neurons, have been classified as nicotinic. The nicotinic receptor represents the primary ganglionic transmission pathway present in all autonomic ganglia, although muscarinic receptors on postganglionic neurons can modulate ganglionic impulse transmission.

Nicotine is not used clinically in animals or humans as a ganglionic blocker; however, several drugs have been discovered that preferentially block autonomic ganglia by a competitive mechanism. These compounds interact with nicotinic neural receptors and block impulse transmission across the ganglionic synapse. Members of this group of ganglionic blocking agents include hexamethonium, pentamethonium, and chlorisondamine.

Because of the blockade of impulse transmission at the ganglia, ganglionic blocking drugs affect physiological responses at targets innervated by postganglionic fibers of the SNS and the PSNS. The overall effects of these agents on various functions are dependent upon the predominance of sympathetic or parasympathetic tone at a particular target, as indicated in Table 8.3 (Taylor, 2006b). Because the GI system functions predominantly under parasympathetic tone, ganglionic blockade often results in decreased motility and reduced secretions. Similarly, because heart rate is under dominant vagal tone, a relative tachycardia may result following ganglionic blockade. Because the smooth muscle tone of peripheral blood vessels is dominated by the SNS, vasodilation and hypotension occur after ganglionic block, and the output of catecholamines from the adrenal medulla is reduced.

Table 8.3 Usual predominance of sympathetic or parasympathetic tone in various tissues and consequent effects of autonomic ganglionic blockade

Structures	Predominant tone	Effects of ganglionic blockade
Eye		
Iris	Parasympathetic	Mydriasis
Ciliary muscle	Parasympathetic	Cycloplegia
Sweat glands	Sympathetic	Anhidrosis
Salivary glands	Parasympathetic	Dry mouth
Cardiovascular		
Arterioles	Sympathetic	Vasodilation: ↑ peripheral blood flow; hypotension
Veins	Sympathetic	Vasodilation: pooling of blood; ↓ venous return
Heart	Parasympathetic	Tachycardia
Gastrointestinal	Parasympathetic	↓ Tone and motility; constipation
Urinary bladder	Parasympathetic	Urinary retention

Anesthetics and Analgesics, and Drugs Acting on the Central Nervous System

9

Introduction to Drugs Acting on the Central Nervous System and Principles of Anesthesiology

Peter J. Pascoe and Eugene P. Steffey

Drugs that act in the central nervous system (CNS) are of fundamental importance to health-care delivery. Some agents are administered to animals to directly improve their well-being. For example, without general anesthesia, modern surgery would not be possible. Some drugs alter behavior and improve animal–human interaction. They may induce sleep or arousal or prevent seizures. Drugs that act in the CNS are sometimes administered in an attempt to understand the cellular and molecular basis for CNS actions (i.e., physiology and pathophysiology) and/or identify the sites and mechanisms of action of other drugs. Finally, CNS actions of some drugs come as unwanted “side effects” when those drugs are used to treat conditions elsewhere in the body. For example, seizures may result from the injection of too much local anesthetic.

The first purpose of this chapter is to review principles of organization and function of the CNS. The intent is to lay a foundation from which later discussion on principles and applied aspects of CNS pharmacology can meaningfully follow. Behavior-altering drugs and anesthetics are routinely administered to animals by veterinarians and allied personnel. Appropriate use of these drugs is an important application of our knowledge of CNS pharmacology. Therefore, this chapter will conclude with a review of the principles of contemporary veterinary anesthesiology.

Introduction to CNS Drugs

Neuroanatomy and Neurophysiology

The CNS is largely the same anatomically across mammalian species. The brain and spinal cord have evolved to collect information about external and internal changes and to provide integration of this information in such a way as to promote the survival and reproduction of the animal. The information is gathered by sensory neurons that transduce a stimulus (e.g., light, sound, gas in the intestine) to an electrical signal (neuronal depolarization) that is transmitted to the central nervous system. The CNS then interprets this signal, computes a response, and initiates an output to effect an appropriate action (if needed). This response may need very little CNS integration or may need much greater interpretation. For example, an animal that steps on a red hot object stimulates a reflex arc to initiate an immediate withdrawal of the limb without any conscious perception that the object was hot. On the other hand a cat faced with a juicy steak sitting on a kitchen counter must first recognize the steak for what it is, and then compare that with its memory for what such an object might taste like and balance this with the memory of the punishment it received the last time it tried to steal such an object from that location. These latter computations involve complex integration in the CNS, and the neuronal involvement is largely controlled by chemical substances that cause, modify, or inhibit the depolarizations that lead to the final outcome.

Although the CNS of most mammals has the same basic organization, it is not surprising that evolutionary pressures have created differences in the relative size of certain components. This is easily demonstrated by examining the olfactory lobes of the brain in a human being and a dog, the latter having a much greater relative size than in people. There are also chemical differences in the CNS of different species that are not as readily explainable but clearly have an impact on our use of drugs to modify CNS activity. It is well known that opioids can cause excitation in horses and sedation in dogs and the distribution of mu and kappa receptors is very different between the two species (Hellyer et al., 2003).

In order to understand how drugs may modify activity within the CNS it is necessary to understand the normal processes that are used to alter interactions between cells within the CNS. To modulate incoming signals, mechanisms are necessary that allow acceptance or rejection of a particular impulse. In a few areas within the mammalian CNS there are neurons that are joined by electrical synapses. These synapses are characterized by tight

connections between the two cells with ion channels that are aligned between the two cells. This arrangement does not allow the receiving cell to change the signal since depolarization of the first cell will result in depolarization of the second cell. However, this arrangement is useful where it is important that a number of cells fire simultaneously to produce a coordinated response and, since the signal can travel in either direction, it enhances the capability of this system to function in this way. The signal is also transmitted much more quickly between the cells (0.1 ms) so it can generate a very rapid response. Brainstem neurons involved in the coordination of breathing have this type of synapse and so do some neurons involved in the secretion of hormones from the hypothalamus. This electrical coordination allows them to produce a "pulse" of hormone by all firing simultaneously.

The vast majority of the neurons in the mammalian CNS, however, communicate by means of chemical signals. The depolarization of the first neuron travels down its axon by virtue of the opening of voltage gated sodium channels (Figure 9.1). At the synapse this wave of depolarization activates voltage-gated calcium channels that allow calcium to flow down the concentration gradient (approximately 10^{-3}M outside the cell to 10^{-7}M inside the cell) into the cytosol of the synapse. The presence of this increased concentration of calcium activates the discharge of vesicles containing a chemical messenger (neurotransmitter) into the synaptic cleft. This neurotransmitter diffuses across the small gap between the neurons and attaches to receptors on the postsynaptic membrane where it might produce one or more of four changes. It might cause a slight depolarization, but not enough to trigger an action potential; it might cause enough depolarization for the generation of an action potential (excitation); it might cause modifications to the internal milieu of the cell such that it could be more or less receptive to further signals (modulation); or it might cause an ionic shift resulting in hyperpolarization of the cell (inhibition). It is then necessary to have some mechanism to terminate that signal so that the postsynaptic neuron can return to its resting state to allow further signals to be received. This can occur by destruction of the neurotransmitter or its uptake into the presynaptic terminal or other surrounding cells.

Transduction

In order for an animal to experience its environment it must be able to convert multiple different forms of incoming energy into neuronal depolarization. This has led to the evolution of a large number of specialized receptors and chemicals that can transduce the incoming signal into something understandable by the animal. Photoreceptors in the eye use rhodopsin and a variety of opsins that are activated by light and amplified by connecting with a G protein-coupled receptor (GRPC). The mechanisms by which the specialized mechanoreceptors in the skin, the Meissner and Paccinian corpuscles, transduce stimuli are still not completely understood. The nerve terminals in these receptors have a variety of potassium and sodium channels that may be involved but the details have yet to be discerned. Nociceptors are known to use multiple receptors to transduce the noxious stimuli into electrical impulses. They respond to direct stimuli such as heat as well as chemical stimuli released from damaged tissue. The transient receptor potential vallinoid (TRPV) family of receptors (TRPV-1, TRPV-2, TRPV-3, TRPV-4) are involved in the transduction of thermal stimuli and respond to specific ranges of temperature (e.g., TRPV-3 responds to temperatures between 31 and 39°C vs. TRPV-1 to temperatures >42°C). The TRPV-1 receptor is also important in peripheral sensitization and in chronic pain states as it is upregulated in these conditions. Capsaicin is a TRPV-1 agonist and, because it continues to activate the channel, may lead to excessive calcium influx into the cell and cell death. In humans, a capsaicin patch has been developed that is applied to localized areas of neuropathic pain (e.g., postherpetic neuralgia) and can significantly reduce pain in some patients for several months after application(Wagner et al., 2013). Another TRPV-1 agonist, resiniferatoxin, has been used to treat osteosarcoma pain in dogs (Brown et al., 2005). There is a great deal of interest in TRPV-1 agonists and antagonists for the treatment of pain but this receptor is also involved in thermoregulation so systemic application of some of these drugs can lead to hyper- or hypothermia. As indicated in Figure 9.1, there are many other receptors on nociceptors and some of these will also tend to hyperpolarize the nociceptor making it less likely to fire. Examples of this include presence of opioid and α_2-adrenergic receptors on some of these neurons, which supports the action of these classes of drugs as peripherally acting analgesics. The peripheral nociceptors are also affected by mediators released as a result of tissue damage. These mediators may not directly cause depolarization but may sensitize the nociceptor to other stimuli leading to the phenomenon of peripheral hyperalgesia. These inflammatory mediators include prostaglandins, bradykinin, histamine, serotonin, cytokines (e.g., IL1β, TNFα), nerve growth factor, purines, endothelin, and protons. Many of these mediators have been pharmacological targets in the management of acute and chronic pain.

Presynaptic Processes

The cellular mechanisms that occur to allow these events to happen are complex and involve many steps. The neurotransmitters involved can be classed into three basic groups: the amino acids, the amines, and the peptides.

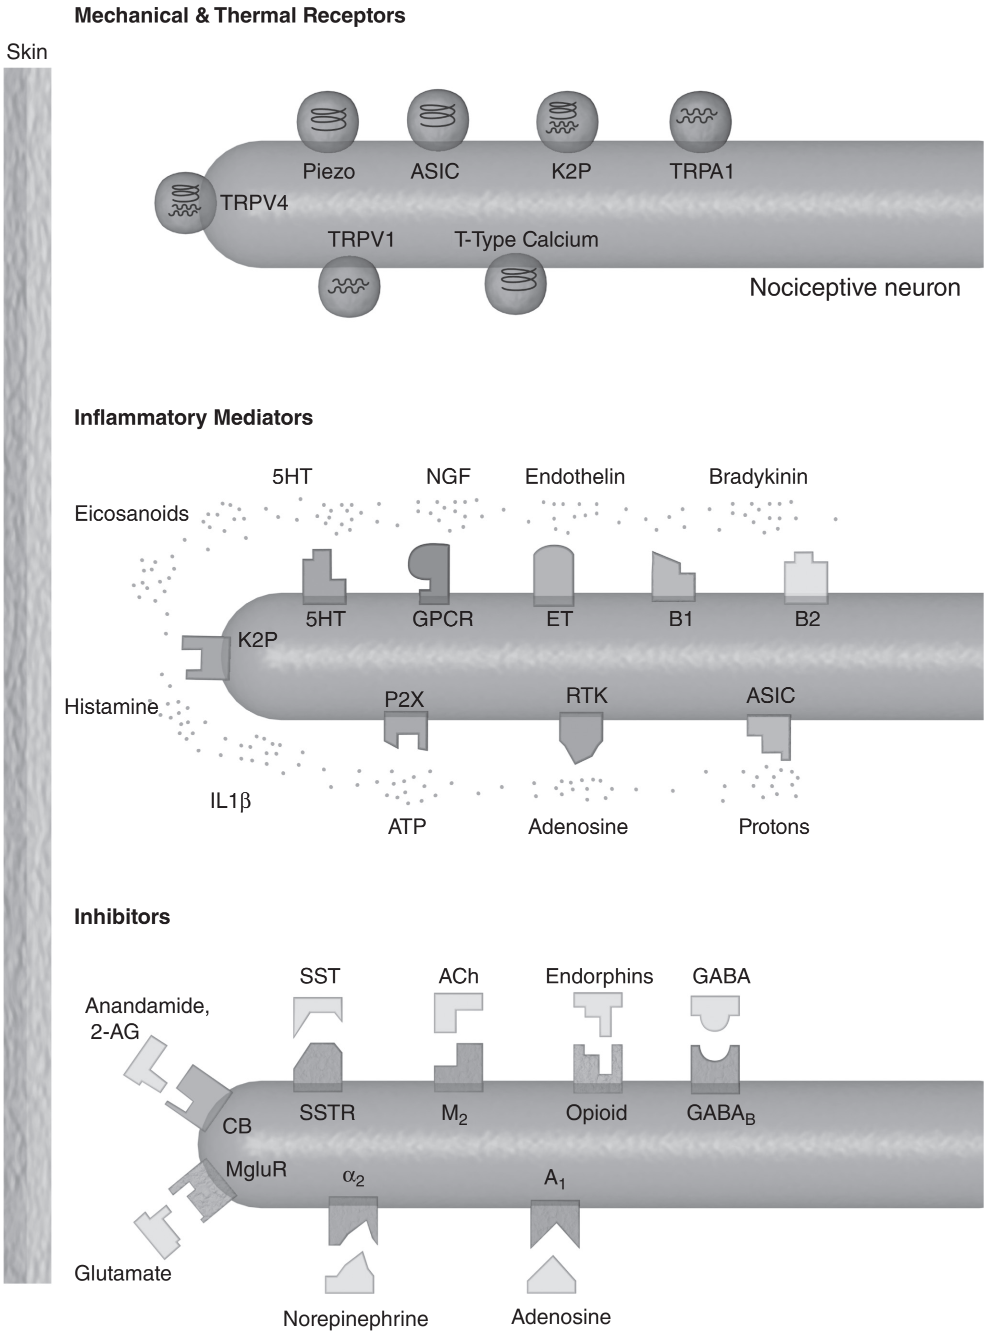

Figure 9.1 Transduction of nociceptive information by free neuronal endings in the dermis. Many receptors are depicted in this figure and it should be recognized that not all nociceptors would have all of these on their surface. (**A**) Receptors that provide direct transduction of thermal (wavy lines) and mechanical (spiral) stimuli. TRPA1, transient receptor potential A1, which responds to noxious cold; K2P, two-pore potassium channel; ASIC, acid-sensing ion channel, which responds to mechanical stimuli as well as protons; Piezo, responds to mechanical stimuli; TRPV4 and TRPV1, respond to hot thermal stimuli; T-Type calcium channel responds to mechanical stimuli. (**B**) Inflammatory mediators that may increase the likelihood of a nociceptor depolarizing. B1 and B2, bradykinin receptors; ET, endothelin receptor; GPCR, G protein-coupled receptor; 5HT, 5-hydroxytryptamine; P2X, purinergic receptor-2X; RTK, receptor tyrosine kinase; NGF, nerve growth factor; IL1β, interleukin-1β; ATP, adenosine triphosphate. (**C**) Inhibitory mediators that may decrease the likelihood of a nociceptor depolarizing. GABA, γ-amino butyric acid; Ach, acetylcholine; M2, muscarinic receptor-2; SST and SSTR, somatastatin and its receptor; CB, cannabinoid receptor; 2-AG, 2-arachidonylglycerol, a cannabinoid agonist; MGluR, metabotropic glutamate receptors; α_2, α-2 adrenergic receptor; A_1, adenosine receptor.

Amino acids can be absorbed from the extracellular fluid but usually involve active transport molecules to achieve this and some are immediately ready to use in this form. The amines and γ-amino-butyric acid (GABA) need to be synthesized from smaller building blocks that require the presence of enzymes. These enzymes are generally made in the cell body and diffuse slowly down the length of the axon to the axon terminal (Figure 9.2). This slow axonal transport occurs at 0.5–5 mm/day. Once an amino acid or amine is present in the nerve terminal it is packaged into synaptic vesicles (40–60 nm in diameter) using an active transporter system. For these small molecules the synaptic vesicles are seen as small clear-core vesicles on electron microscopy. The peptides, on the other hand, are manufactured in the cell body and packaged into larger vesicles at this site. They are actively transported to the axon terminal using microtubules and ATP-requiring proteins such as kinesin to achieve this (Figure 9.2). These large dense-core vesicles (appearance on electron microscopy) move at about 400 mm/day down the axon, so this occurs much faster than the diffusion of the enzymes needed for GABA and amine production. The synaptic vesicles tend to cluster around dense areas of the synaptic membrane (called *active zones*) that contain the necessary proteins to achieve transmitter release. The active zones have calcium channels that provide the stimulus for activation of the cascade required for docking and exocytosis of the synaptic vesicle. One

Post-synaptic receptors

Figure 9.2 Neuron that is involved in chemical transmission. Enzymes and peptides are made in the cell body and transported to the axon terminal. The transport of enzymes is slow, whereas peptide synaptic vesicles are transported actively down the microtubules. Neurotransmitters are packaged into synaptic vesicles and these accumulate near the synaptic cleft. When the cell depolarizes the synaptic vesicles merge with the outer cell membrane and release neurotransmitter into the synaptic cleft. This chemical acts on the receptors on the postsynaptic membrane to alter postsynaptic cell function. Some neurotransmitters are destroyed in the cleft, some are reabsorbed into the axon terminal, and some may be absorbed by neighboring glial cells and destroyed or recycled into the axon terminal.

family of these proteins, referred to as the SNARE proteins (soluble *N*-ethylmaleimide attachment protein receptors) form complexes between the synaptic vesicle and the cell membrane (docking) and help promote the next step in the process (fusion of the membranes) so that the contents of the vesicle can be ejected into the synaptic cleft (exocytosis). These proteins are cleaved by botulinum and tetanus toxin, thus preventing neurotransmitter release (Breidenbach and Brunger, 2005). In the case of botulinum toxin, this effect remains peripheral at the neuromuscular junction whereas tetanus toxin is transported to the CNS where its effects occur mainly in inhibitory neurons, thus explaining the different manifestations of the two diseases (paralysis with botulinum and muscular rigidity with tetanus). The synaptic vesicles may then be reformed (endocytosis) with the aid of proteins called *clathrins* and recycled to be filled again with more neurotransmitter. The whole process from formation, exocytosis to endocytosis, and refilling of these synaptic vesicles can be carried out in about 1 minute, thus enabling frequent signaling from the terminal. Many synaptic terminals contain both small clear-core (amino acids and amines) and large dense-core vesicles (peptides). The peptide-containing vesicles are not usually released as readily as the clear-core vesicles and require a greater concentration of intracellular calcium for their release (usually the result of rapid repetitive depolarization of the neuron), thus providing the potential for a different signal to be associated with a more intense stimulus. Many presynaptic terminals have receptors on them that respond to the neurotransmitter being released (autoreceptors). This is usually presented as a feedback loop, which results in the inhibition of further release of the neurotransmitter.

Postsynaptic Processes

The receptors on the postsynaptic membrane can be divided into two types: the ionotropic or ligand-gated receptors and the metabotropic receptors. Ionotropic receptors allow the immediate passage of an ion across the cell membrane. For the most part, these are proteins that allow passage of sodium, calcium, potassium, or chloride. The metabotropic receptors activate a process inside the cell that may alter ionic conduction through another channel or they may alter the production of other substances within the cell that could change how the cell reacts to further stimulation. This process is very powerful because it can amplify the initial signal received. One receptor might activate a cellular enzyme that then catalyzes the production of many molecules, and each of these may further amplify the effect by activating further reactions. Normally, the signal from an ionotropic receptor is seen almost immediately, whereas the effect from a metabotropic receptor may take longer and may last longer after the stimulus.

In the CNS an individual neuron may receive input from hundreds of other neurons. Each synapse with its neurotransmitter can either excite (increase the resting membrane potential toward 0) or inhibit (decrease the resting membrane potential to a more negative value). The final effect on that individual neuron will be a result of the type of input it receives and the relative timing of that input. If there is simultaneous input from several excitatory neurons at the same time, it is likely that the neuron will depolarize and send a signal on to the next cell in the pathway. This is referred to as spatial summation. On the other hand, if a single input kept on firing it might achieve enough depolarization to trigger an action potential. This is referred to as temporal summation. If this neuron had received several signals from inhibitory neurons during this period the magnitude of the excitatory signal would have to be greater in order for the neuron to achieve a threshold for the action potential. Note, however, that inhibition under these conditions is not normally absolute and that if a strong enough stimulus is applied it will overcome the inhibition.

The attachment of a neurotransmitter to a receptor could be followed by a number of events. The receptor could have an effect and then the neurotransmitter and the receptor could be absorbed into the cell, thus terminating this effect (receptor internalization). The neurotransmitter could be destroyed by a chemical reaction catalyzed by an enzyme located nearby in the synaptic cleft. Some of the fragments of the molecule could then be absorbed again into the presynaptic terminal and reassembled into the original neurotransmitter while some fragments diffuse into the surrounding extracellular fluid. Lastly, the molecule could diffuse off the receptor as the concentration gradient reverses and it could be taken up into the presynaptic terminal or into surrounding glial cells for further transport back into the presynaptic terminal. These actions usually require the presence of transporter proteins for maximal efficiency.

The Neurotransmitters and their Receptors

There are a number of criteria for establishing a chemical as a neurotransmitter and a great deal of effort has been taken to ensure that these criteria are met by potential candidates. Just finding a chemical in the CNS does not mean that it is a neurotransmitter.

1) The substance must be present in the presynaptic terminal.
2) The substance must be released into the synaptic cleft when the presynaptic terminal depolarizes. In most instances this should be dependent on the intracellular release of calcium.

3) There should be receptors for the substance on the postsynaptic membrane that can be activated by exogenous placement of the substance on those receptors.

In the past, this kind of proof was difficult to obtain because an individual synapse is so small and being able to record from it is so technically challenging. Even with molecular biological techniques it is not simple but there have been a number of instances where a receptor has been discovered before the neurotransmitter that binds to it.

The Amino Acids

Glutamate: Glutamate is generally considered to be an excitatory neurotransmitter and is used in about half of the synapses in the brain. It is a nonessential amino acid that does not cross the blood–brain barrier so it has to be synthesized by the neuron (Table 9.1). Once it has been released into the synaptic cleft it is removed via a high-affinity uptake process on the presynaptic terminal and local glial cells involving excitatory amino acid transporters (EAATs). So far, five of these EAATs have been identified and their locations in the brain and relative activities vary (Bridges and Esslinger, 2005). The glutamate taken up in glial cells is converted to glutamine, which can then be absorbed by the presynaptic terminal and converted back to glutamate. Both EAATs and vesicular glutamate transporters (VGLUTs) have become targets for pharmacological manipulation. Glutamate acts on three families of ionotropic receptors and three classes of metabotropic receptors. The ionotropic receptors are named after the agonists that were first shown to activate them: *N*-methyl D-aspartate (NMDA receptor); α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA receptor); and kainate (kainate receptor). As with most of these receptors, they are composed of four or five subunits of membrane-spanning proteins and this gives rise to the possibility of many forms for each receptor (Table 9.1). These variations provide a basis for pharmacological targeting of individual receptors. The metabotropic receptors are divided into three classes, with class I (mGluR1 and 5) acting via $G_{q/11}$ proteins to increase phospholipase C (excitatory) and classes II (mGluR2–3) and III (mGluR4, mGluR6–8) acting via G_i/G_o proteins to inhibit adenylyl cyclase activity (inhibitory). So, although the major effects of glutamate are excitatory, there are parts of the brain where it can act as an inhibitory neurotransmitter. The NMDA receptors are important in the practice of anesthesia and analgesia because drugs that are antagonists at this receptor (cyclohexanones such as ketamine and tiletamine) are commonly used. At least six binding sites have been identified on the NMDA receptor for pharmacological activity. The site that binds glutamate (1) opens the channel to the entry of sodium and calcium into the cell. This site appears to need glycine to be bound to the receptor (2) for the glutamate to be fully effective. A third site within the channel binds phencyclidine and other cyclohexanones (3). There is also a voltage-gated magnesium binding site (4) within the channel; the ejection of magnesium from this site with depolarization opens the channel for further activity. There are also an inhibitory divalent site that binds zinc (5) near the mouth of the channel and a polyamine regulatory site (6) that potentiates the currents generated from the receptor when it is activated. The NMDA receptor is thought to affect long-term potentiation, memory, and plasticity of the nervous system. Long-term potentiation is likely involved with the modulation of nociceptive input. Activation of the receptor is also involved in the process of excitotoxicity leading to neuronal death.

Glycine: This is an inhibitory neurotransmitter, which is found in high concentrations in the medulla and spinal cord. Because glycine is found in all tissues in the body it has been difficult to isolate its activity in the CNS. The glycine receptor is a pentameric structure, and four α-subunits and one β-subunit have been identified. It is a ligand-gated chloride channel allowing the ingress of chloride ions, making the inside of the cell more negatively charged (hyperpolarization). The glycine and strychnine binding sites are located on the α_1 subunit. Once released into the synaptic cleft, glycine is taken back up into the presynaptic terminal or into surrounding glial cells by an active transporter for glycine (GLYT1-2), with GLYT-2 being the version mainly expressed on neurons. As indicated above, glycine interacts with glutamate at the NMDA receptor and GLYT is found in those neurons despite a lack of glycine receptors.

GABA: This is the major inhibitory neurotransmitter within the CNS and is present in as many as one-third of all synapses in the CNS. By comparison with its concentrations in the CNS it is found only in trace amounts elsewhere in the body. GABA is made from L-glutamic acid and this reaction is catalyzed by glutamic acid decarboxylase (GAD); this irreversible reaction needs a cofactor – pyridoxal phosphate (PLP a form of vitamin B_6). There are two forms of GAD (GAD_{65} and GAD_{67}) and GAD_{65} has a higher affinity for PLP, making its activity more easily regulated. GABA is broken down to succinic semialdehyde by GABA-transaminase (GABA-T), which also requires PLP and this can then enter the Krebs cycle via further breakdown to succinic acid. Since both GAD and GABA-T are dependent on PLP, a diet deficient in vitamin B_6 can lead to a decreased level of GABA in the brain with resulting seizures. GABA may be broken

Table 9.1 Small molecule neurotransmitters with their origins, transport proteins, method of catabolism, and receptors

Neurotransmitter	Synthesized from	Transport of raw material into presynaptic terminal	Rate-limiting step in synthesis	Vesicle transport	Reuptake	Catabolism	Ionotropic receptors	Metabotropic receptors and associated g protein
Glutamate	Glutamine or α-oxoglutarate	Excitatory amino acid transporter (EAAT)		Vesicular glutamate transporter (VGLUT)	EAAT1–5	Glutamine synthetase	NMDA (NR1, NR2A–D)	Class I (mGluR1&5) $G_{q/11}$
							AMPA (Glu R1–4)	Class II (mGluR2–3) G_i/G_o
							Kainate (Glu R5–7, KA1–2)	Class III (mGluR4, mGluR6–8) G_i/G_o
Glycine	Serine?		Serine trans-hydroxymethylase & D-glycerate dehydrogenase		Glycine transporter (GLYT1–2)		Glycine (α_{1-4}, β subunits)	None
GABA	L-glutamic acid	EAAT	Glutamic acid decarboxylase (GAD_{65} and $_{67}$)	Vesicular GABA transporter (VGAT)	GABA transporters (GATs)	GABA transaminase	$GABA_A$ and $_C$	$GABA_B$ G_i
Acetylcholine	Choline and acetyl CoA	High affinity transporter	Choline transport	Vesicular acetylcholine transporter	High affinity transporter of choline	Acetylcholinesterase (AChE)	Nicotinic AChRs (α_{2-9}, β_{1-4}, γ, Δ subunits)	Muscarinic (M1–5) $G_{q/11}$ – M1, M3, M5 G_i – M2, M4

down into a number of other metabolites including γ-hydroxybutyric acid (GHB). There is some evidence that the breakdown to GHB is a reversible response and that GHB might be used in the brain to make GABA. GHB has been used in anesthesia and is now an abused street drug; part of its action might be to promote the production of GABA, although a specific GHB receptor is proposed, and GHB is a micromolar (exogenous administration) agonist at the $GABA_B$ receptor and a nanomolar agonist at α4βδ $GABA_A$ receptors.

Once GABA is released into the synaptic cleft its action is terminated mainly by reuptake into the presynaptic terminal using GABA transporters. Some GABA is taken up into surrounding glial cells using the same mechanism but there does not appear to be a mechanism for transfer of this GABA back to the neuron, so the latter must synthesize more GABA to make up for the amount lost. The GABA receptors are divided into an ionotropic group ($GABA_A$, $GABA_C$) and a metabotropic group ($GABA_B$). The $GABA_A$ receptor (Figure 9.3) is a ligand-gated chloride channel and when activated will tend to hyperpolarize the cell. It contains four subunits, and at least 21 proteins (α_{1-7}, β_{1-4}, γ_{1-4}, Δ, ε, θ, ρ_{1-3}) have been identified that can be used to make up this receptor, giving it a great deal of structural diversity. It has been shown that some of these variations have different relative sensitivities to GABA providing the potential for different levels of response to release of the same neurotransmitter. The inhalant anesthetics may activate the $GABA_A$ receptor but this is unlikely to be the only site of action. Propofol and etomidate enhance the action of GABA at the receptor at low concentrations and directly activate the $GABA_A$ receptor at higher concentrations, while barbiturates are much less selective for this receptor. The benzodiazepines have a separate binding site on the receptor that enhances the opening of the channel when natural GABA attaches to its binding site (Figure 9.3). Alfaxalone may affect the GABA receptor by binding to the transmembrane portion of the receptor (Akk et al., 2009). The $GABA_B$ receptor is coupled to G_i proteins that are indirectly linked to potassium channels (increased conductance) and calcium channels (decreased conductance). The latter effect is important for $GABA_B$ receptors located on the presynaptic membrane since this will decrease the amount of calcium released into the cell following an action potential and therefore decrease the release of GABA from the terminal (autoinhibitory response). It is thought that baclofen reduces GABA release via this mechanism.

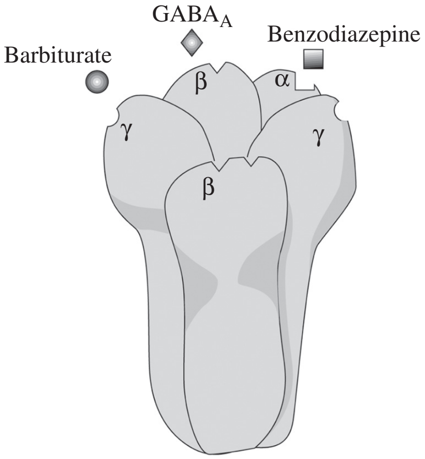

Figure 9.3 $GABA_A$ receptor showing the pentameric structure and protein subtypes that make up the receptor. Neurotransmitters and drugs attach to different subunits on the receptor.

The Amines

Acetycholine: Acetylcholine (ACh) is synthesized from choline and acetyl coenzyme A (acetyl CoA) in a reaction catalyzed by choline acetyltransferase (ChAT). Choline is mainly derived from the blood and from the phospholipid, phosphatidylcholine, and is transported into cells by a high-affinity transporter. Acetyl CoA is derived from glucose or citrate in the mammalian CNS. The synthesized ACh is packed into vesicles via a vesicular acetylcholine transporter. Once released into the synaptic cleft, the ACh attaches to a receptor. In the CNS most of these are nicotinic receptors (nAChRs), another group of pentameric proteins with multiple possible subunits (α_{2-9}, β_{1-4}, γ, Δ). These are nonspecific ion channels that are excitatory. Some areas of the CNS, especially the forebrain and striatum, also contain muscarinic receptors that are metabotropic G protein-coupled receptors (M1–5). Activation of these receptors has an inhibitory effect on dopamine-mediated motor responses. The synaptic cleft also contains acetylcholinesterase (AChE), which is a highly efficient enzyme (5,000 molecules of ACh hydrolyzed/ second/ molecule AChE) that promotes the breakdown of ACh to choline and acetic acid. The choline is taken back up into the nerve terminal for remanufacture to ACh. Atropine acts on central muscarinic receptors but is not specific to any one subtype. Organophosphates block the action of AChE, thus allowing accumulation of ACh in both the PNS and CNS. This leads to typical signs of parasympathetic activation—salivation, lacrimation, urination, diarrhea, and bradycardia – but may also be accompanied by convulsions and eventually coma and death.

Dopamine: Dopamine is synthesized from tyrosine, with tyrosine hydroxylase (TH) catalyzing the conversion of tyrosine to L-DOPA and DOPA decarboxylase catalyzing the conversion to dopamine. The production of an activated phosphorylated TH is dependent on calcium ion concentration, cyclic AMP, and a tetrahydrobiopterin (BH_4). The latter binds to a site on TH that can also bind dopamine, so increasing concentrations of dopamine will inhibit the production of more dopamine. Dopamine is packed into synaptic vesicles by a vesicular monoamine transporter (VMAT) and can then be released into the synapse from these vesicles. Termination of the action of dopamine is mainly by reuptake into presynaptic terminals by a dopamine transporter (DAT). The resorbed dopamine is converted to dihydroxyphenylacetic acid (DOPAC) by monoamine oxidase in the nerve terminal. Dopamine taken up by surrounding glial cells is converted to homovanillic acid by catecholamine-*O*-methyltransferase (COMT). There are species differences in the relative importance of these reactions.

Dopamine receptors can be divided into two forms, D1 and D2-like. Dopamine1 and D5 are classed together and D2–4 are the D2-like receptors. These are all metabotropic G protein-coupled receptors. The D1 receptors are linked to a G_s protein that increases the cellular concentration of cAmp while the D2 receptors are linked to a G_i protein having the opposite effect. D1 receptors are generally found on postsynaptic membranes and while D2 receptors are present on some postsynaptic sites they are more commonly found as autoreceptors on the presynaptic membrane. At this site they seem to be able to affect both synthesis and release of dopamine from the nerve terminal.

Dopamine is found in a number of regions of the brain but its presence in the corpus striatum is thought to play a major role in motor coordination and locomotion. Dopamine is also involved with reward, reinforcement, and motivation, and it is this aspect that contributes to its role in drugs of addiction. For example, cocaine inhibits DAT, thus prolonging the presence of dopamine in the synaptic cleft and prolonging its action on the postsynaptic membrane. Phenothiazines are thought to be dopamine antagonists and hence they reduce motivation and action while monoamine oxidase inhibitors will increase dopamine release and are used in the treatment of depression. Drugs that block D2 receptors will decrease the release of dopamine and at high enough doses will produce catalepsy.

Norepinephrine and epinephrine: These are much less important neurotransmitters within the CNS compared with dopamine (about one-quarter to one-third of the number of neurons containing dopamine) but are also involved in wakefulness, attention, and feeding behavior. These neurotransmitters play a dominant role in autonomic nervous system function, and were fully described in Chapter 7. Norepinephrine is produced from dopamine with the aid of dopamine-β hydroxylase and epinephrine is further synthesized with the aid of phenylethanolamine-*N*-methyltransferase. The latter is found in a discrete number of neurons that are different from those secreting norepinephrine. Both neurotransmitters are packed into vesicles using VMAT and are metabolized by monoamine oxidase and COMT when taken back up into the cell. Norepinephrine is removed from the synaptic cleft by norepinephrine transporter (NET) and this will also transport epinephrine – no specific epinephrine transporter has been identified.

The α- and β-adrenergic receptors for these neurotransmitters are G protein-coupled metabotropic receptors and are further divided into α_{1A-D}, α_{2A-C}, and β_{1-3}. The α_{1A-D} are associated with a G_q protein that results in a slow depolarization due to the inhibition of K^+ channels while the α_{2A-C} receptors are associated with a G_i protein that results in hyperpolarization. The α_2 receptors are found on both presynaptic and postsynaptic terminals. They act as autoreceptors on the presynaptic terminal to decrease the release of norepinephrine. Since wakefulness is dependent on tonic activity on these neurons it follows that the inhibition of this activity would tend to lead to sedation and lack of movement. This is the principle behind the use of α_2 agonists, which decrease the release of norepinephrine and may hyperpolarize the postsynaptic cells as well. α_2 antagonists have the opposite effect and can cause central excitation when administered alone.

Histamine: Histamine is produced from the amino acid histidine, catalyzed by the enzyme histidine decarboxylase. It is transported into vesicles using VMAT and released into the synaptic cleft where it can act on one of three histamine receptors (H_{1-3}). Chapter 19 should be consulted on histamine's role outside of the CNS. No plasma membrane transporter has been identified for histamine but it is metabolized by histamine methyltransferase and monoamine oxidase. The histamine receptors are G protein-coupled metabotropic receptors. H1 is coupled with a G_q protein affecting inositol phospholipase, H2 is coupled with a G_s protein that increases the cAmp concentrations, while the H3 receptor is coupled with a G_i protein with opposing effects. It is thought that the H3 receptor is the autoreceptor on the presynaptic terminal involved in decreasing the release of histamine and possibly other neurotransmitters present in the same cells.

Histamine is also thought to be involved in aspects of wakefulness and is strongly associated with the vestibular apparatus, explaining the use of antihistamines in the control of motion sickness and that drowsiness is a common effect with antihistamines that cross the blood–brain barrier.

5-Hydroxytryptamine or serotonin: 5-Hydroxytryptamine (5-HT) is synthesized from tryptophan via 5-hydroxytryptophan catalyzed by the enzymes tryptophan-5-hydroxylase and then aromatic L-amino acid decarboxylase. Tryptophan is transported into the brain via an active process that also transports other large neutral amino acids. This means that the production of 5-HT is dependent not only on the concentration of tryptophan in the diet but also on the relative amounts of tryptophan. Dietary restriction of tryptophan depletes 5-HT production while increased dietary tryptophan increases 5-HT production up to a point where the tryptophan-5-hydroxylase enzyme system becomes saturated. As with many biological systems a treatment that alters one component may be compensated for by changes in another component. For example, increased dietary tryptophan could be compensated for by a decrease in tryptophan-5-hydroxylase. Once synthesized 5-HT is packed into vesicles using VMAT and once released, it is transported back into the cell by a specific 5-HT transporter (SERT). This protein is the target for a number of therapeutic agents called the *selective serotonin reuptake inhibitors (SSRIs)*, of which fluoxetine (Prozac) is one. Once taken up, 5-HT is mainly broken down using monoamine oxidase.

At least 12 5-HT receptors have been identified (5-HT$_{1A-E}$, 5-HT$_{2A-C}$, 5-HT$_{3-7}$), with the majority being G protein-coupled metabotropic receptors. The exception to this is 5-HT$_3$, which is a ligand-gated ionotropic receptor that allows influx of cations to cause excitation of the postsynaptic membrane. The 5-HT$_1$ receptors are coupled with G$_i$ proteins and 5-HT$_2$ with G$_q$ proteins, and the others are thought to be associated with G$_s$ proteins (with the exception of 5-HT$_5$, which is probably associated with a G$_i$ protein).

5-HT is also involved in the regulation of sleep and attention and it plays a role in nociception and the control of emesis. Some potent antiemetics such as ondansetron and granisetron are 5-HT$_3$ antagonists. The 5-HT$_3$ receptor may be involved in the mechanism of action of inhaled anesthetics (Solt et al., 2005; Stevens et al., 2005). Serotonin syndrome is a condition described in people that presents with multiple signs, including alterations in conscious state (agitation, anxiety, seizures to lethargy, and even coma), autonomic dysfunction (central and peripheral actions of 5-HT hyperthermia, sweating, tachycardia, hypertension, dyspnea, dilated pupils), and neuromuscular changes (myoclonia, hyperreflexia, and ataxia). This syndrome is being reported more commonly because of the many drugs being prescribed that affect the 5-HT system. Amitriptyline, tramadol, meperidine, and St John's wort all reduce 5-HT uptake, while selegiline and St John's wort reduce 5-HT catabolism. Combinations of these drugs or excessive doses of a single agent can lead to this syndrome (Jones and Story, 2005). In dogs a similar syndrome has been described following ingestion of 5-hydroxytryptophan (Gwaltney-Brant et al., 2000).

Peptides

Many peptides have been identified as playing a part in neurosignaling. These substances are synthesized in the cell body as a prepropeptide that may contain a number of different peptide molecules. Proopiomelanocortin (POMC) is a good example since it contains ACTH, α- and γ-melanocyte stimulating hormone (MSH), γ-lipotropic hormone, and β-endorphin. The final peptide neurotransmitter is generated by peptidases cleaving the prepropeptide into its component parts and this cleavage may be tissue specific. In the anterior lobe of the pituitary, POMC is converted mainly to ACTH, whereas the output from the intermediate lobe consists mainly of β-endorphin and MSH. Most of the peptides are colocalized in synaptic terminals with smaller molecule neurotransmitters (Table 9.2) and their release may be dependent on a different signal strength than with the smaller molecules. Typically, it takes a greater amount of calcium in the synaptic vesicle to get the peptide to be released. Once the peptide has been released it attaches to receptors on the postsynaptic membrane and it generally takes lower concentrations of these molecules, compared with the smaller neurotransmitters, to have an effect. A peptide may also diffuse more broadly to influence neurons further away as suggested by the fact that receptors for some peptides are in separate anatomical locations to the neurons producing the peptidergic agonist. As for the other neurotransmitters, peptide receptors often come in a variety of subtypes and these may be found in different locations of the CNS and subserve different signaling purposes. They are all G protein metabotropic receptors. Once released into the synaptic cleft the peptides are

Table 9.2 Colocalization of some small molecule neurotransmitters with peptides

Neurotransmitter	Peptides found in the same terminals
Glutamate	Substance P Orexin Enkephalin

Angiotensin	AT$_{1,2}$
Neurotensin	NTS$_{1,2}$
Corticotropin releasing factor (CRF)	CRF$_{1,2}$
Calcitonin gene-related peptide (CGRP)	CGRP$_1$, AM$_{1,2}$
Bradykinin	B$_{1,2}$

catabolized by peptidases that are present in the extracellular matrix.

The peptides can be divided into several groups, which have more to do with their discovery than their function within the CNS: the gut/brain peptides, the pituitary hormones, the hypothalamic releasing factors, the opioid peptides, and others (Table 9.3). Of these, the tachykinins (specifically substance P) and the opioids are the most important with regard to nociception. Substance P is colocalized with glutamate in many of the small fiber afferents that are involved with sensing hot/cold and noxious stimulation and it attaches to one of the neurokinin receptors (NK$_{1-3}$). Opioid peptides (β-endorphin, dynorphin, leu-enkephalin, met-enkephalin, α and β neoendorphin, orphanin FQ) act at the mu, kappa, delta, or orphanin FQ receptors (MOP, KOP, DOP, and NOP). These peptides are present in the dorsal horn of the spinal cord and throughout the CNS, and are largely involved in the modulation of nociception. The relative abundance and location of these peptides and their receptors varies between species.

Other Neurotransmitters

Purines: ATP, adenosine, and adenine dinucleotides are released into the synaptic cleft of some neurons. These differ from classic neurotransmitters in that ATP and adenine dinucleotides may be in the same synaptic vesicle as other small molecule neurotransmitters, while adenosine is not stored in vesicles. Further ATP can be converted to adenosine in the synaptic cleft to act on its receptors separately from the ATP. Adenosine attaches to P$_1$ receptors (A$_1$, A$_{2A-B}$, A$_3$), which are all G protein-coupled receptors; ATP can attach to P$_{2X1-5}$ (ionotropic) or P$_{2Y1,2,4,6,11}$ (metabotropic) receptors. Adenosine has hypnotic and anxiolytic effects and is involved in the modulation of nociception.

Endocannabinoids: Anandamide and 2-arachidonylglycerol (2-AG) are thought to act on cannabinoid receptors (CB1-2). This is an unusual signaling pathway because the ligands are released from the postsynaptic cell and have an effect on the presynaptic terminal. The current hypothesis is that the increase in postsynaptic cytoplasmic calcium, triggered by depolarization, stimulates the release of the cannabinoid neurotransmitter and this attaches to CB1 receptors on the presynaptic terminal resulting in an inhibitory effect. The CB1 receptors are located on GABA terminals so the inhibition of GABA release reduces the inhibitory effect of GABA and causes stimulation (e.g., increased appetite associated with cannabis administration).

Agmatine: Agmatine is a decarboxylated arginine that has been found as an endogenous neurotransmitter and has been proposed as a natural agonist at the imidazoline receptor. These receptors are of interest to the clinician because many of the α$_2$ agonists used in practice are imidazolines (e.g., medetomidine, detomidine, romifidine). However, investigations with this substance have also shown that it interacts with the glutmatergic system and acts as an antagonist at the NMDA receptor and inhibits nitric oxide synthase. Given its colocation in multiple sites it is thought to be more of a cotransmitter rather than the primary imidazoline agonist. Agmatine has been shown to be able to decrease pain resulting from inflammation, neuropathy, and spinal cord injury (Fairbanks et al., 2000) and may have many other therapeutic effects (Piletz et al., 2013).

Role of Nonneuronal Cells

The normal development and activity of the CNS is dependent on the glial cells. The three types of glial cells – oligodendrocytes, astrocytes, and microglia – are all intimately associated with neurons. The oligodendrocytes form myelin sheaths for neurons in the CNS (equivalent to the Schwann cells in the PNS), the astrocytes ensheath synaptic junctions, provide a scaffolding within the CNS, and ensheath the capillaries as part of the blood–brain barrier. Microglia are present throughout the CNS and were thought to be relatively quiescent until needed to provide clean-up duties by engulfing foreign materials and pathogens. It is now clear that all of these cells also have a function in cell-to-cell signaling even though they do not have the ability to depolarize. As indicated above in this section, astrocytes that surround the synaptic junctions play a role in absorbing neurotransmitters and, in some cases, metabolizing them and/or transferring them back to the presynaptic terminal. Some of these molecules may also activate the glial cells – substance P, ATP, and excitatory amino acids have all been shown to do this. Other substances that may be released from the neuron to activate the glia include nitric oxide and fractalkine. Disturbingly, it has also been shown that morphine can activate glial cells and so the administration of an opioid analgesic may be enhancing the transmission of nociceptive information (Watkins et al., 2005)! However, the depolarization of the synaptic terminal itself may also activate the astrocyte and open calcium channels. An influx of calcium into the astrocyte may induce increased production of factors that can feed back to the synapse or this change may be transmitted to other astrocytes via the tight junctions that connect these cells. Factors released by glia that might alter synaptic transmission include prostaglandins, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), the neurotrophins NT-3 and NT-4/5, and the proinflammatory cytokines interleukin-1 (IL-1) and tumor necrosis factor (TNF). As an example, it has been shown that BDNF activates a specific sodium channel on some neurons and this plays a role in long-term potentiation. Thus the glial cells may release factors into their local environment that affect the activity of a number of neurons, adding an amplifying effect to signals being processed through this network. Using drugs that modify the activation of glial cells (e.g., minocycline) or drugs that block cell signaling pathways internally (e.g., p38 MAP kinase inhibitors) or the production of activators (e.g., antiprostaglandins) has the potential to alter pain perception.

Interactions Between Neurotransmitter Systems

The descriptions above are overly simplistic in many areas since there are multiple interactions between the neurotransmitters and the processes that control them. The colocation of neurotransmitters within the same presynaptic terminals means that even the signal produced from a single terminal can be modified by the intensity of the incoming signal or other chemicals in the local environment. It is also being shown that receptor proteins can interact directly to modify the signal being received. For example, D5 interacting with $GABA_A$ and D1 with NMDA. In the latter case activation of D1 receptors decreases the cell-surface localization of NMDA receptors, whereas activation of the NMDA receptor increases the number of D1 receptors on the cell surface (Lee and Liu, 2004).

Blood–Brain Barrier

In order for any drug to produce an effect on the CNS it has to gain access to the neurons and other cells in the brain. Neuronal function relies on having a very stable extracellular ionic content and limiting the number of “foreign” substances to a minimum, such that exposure of neurons to nanomolar concentrations of some neurotransmitters can produce an effect. In order to achieve this, animals have developed a barrier from the blood that allows the passage of small molecules but restricts the passage of ionic compounds and most larger molecules (Abbott, 2005; Hawkins and Davis, 2005). This barrier is formed by tight junctions between endothelial cells, pericytes, a basement membrane, and by astrocytes that encase the capillaries (Figure 9.4). As well as the tight junctions the endothelial cells have an increased content of mitochondria, a lack of fenestrations, and minimal pinocytotic activity compared with capillaries in other parts of the body. The barrier is not present in some areas of the brain, namely, the circumventricular organs (CVOs). These include the subfornical organ at the roof of the third ventricle, the median eminence and the organum vasculosum of the lamina terminalis in the floor of the third ventricle, the pineal gland and the subcommissural organ at the back of the third ventricle, and the area postrema near the fourth ventricle. The chemoreceptor trigger zone (CTZ) is in the area postrema and its lack of a blood–brain barrier (BBB) may be part of the explanation for the rapid onset of emesis with some opioids (e.g., morphine). These drugs produce an antiemetic effect at the vomiting center, which is behind the BBB, and so the resultant effect is dependent on the rate at which the drug activates these two areas. With hydrophilic drugs, penetration to the vomiting center is slower than the effect on the CTZ with resulting emesis. More lipophilic opioids (e.g., fentanyl) inhibit the vomiting center at about the same time as they excite the CTZ, giving a much lower incidence of emesis. These CVOs have a comparatively small surface area and are thought to be separated from the rest of the brain by a glial barrier, thus limiting the spread of material taken up through the CVOs. The choroid plexus is comparatively leaky, but substances that gain access to the CSF have relatively limited access to neuronal tissue. The

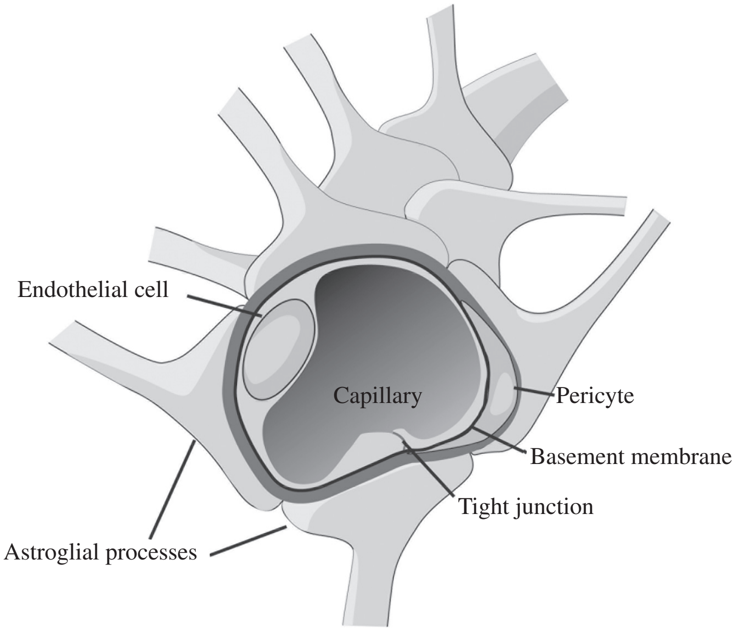

Figure 9.4 Blood–brain barrier. The endothelial cells have tight junctions that link the cells in such a way as to minimize passage of material through the cells. These cells also have fewer pinocytotic vesicles and more mitochondria than capillary endothelial cells elsewhere in the body. These cells are surrounded by a basement membrane and there are pericytes in this location. Astroglial foot processes surround the outside of the capillary.

surface area of the choroid plexus is about 1/1000th of the area of the BBB.

The transfer of molecules across the BBB under normal physiological conditions is regulated by three factors. There are solute carrier (SLCs) proteins that are used to carry essential molecules such as glucose, amino acids, amines, adenine, adenosine, vitamins, and thyroid hormones across the barrier. Over 350 of these SLCs have been identified and they are referred to using a number and letter system (e.g., SLC7A5, SLC47A2). There are receptor-mediated methods involved in the transcytosis of some peptides. Insulin, transferrin, and leptin are examples of peptides that are transferred by receptor-mediated transcytosis. There are also ATP-binding cassette (ABC) transporters that move substances in both directions across the BBB. There are seven subfamilies of these ABC transporters and they play a role in many tissues in the body, as introduced in Chapter 2. The seven subfamilies are designated by letters (e.g., ABCA1, ABCB2, ABCG2). The ABC transporters move substances in both directions depending on their location on the luminal side of the endothelial cell (ejecting substance) or the abluminal side of the cell, where they may be part of an active transportation of molecules into the brain. The best studied are the active efflux systems that are designed to eject unwanted metabolites from the extracellular space in the brain and have now been shown to have significant effects on the access of some drugs to the CNS. One of the proteins involved in this process is ABCB1 or P-glycoprotein, which has a wide substrate specificity and transports a range of drugs from the CNS. This has become of clinical interest with the discovery of the *MDR-1* gene that is responsible for the production of ABCB1. In some herding breed dogs (Collies and Australian Shepherds) a polymorphism of this gene results in increased toxicity to a number of drugs that was first recognized as ivermectin toxicity (Mealey, 2004). It is now evident that a lack of ABCB1 may also alter the brain concentration of a number of other drugs. In *MDR-1* deficient mice, brain concentrations of morphine and fentanyl were increased by 25% and the uptake of methadone was increased by 200–1500% (Dagenais et al., 2004; Wang et al., 2004). Butorphanol may have a more profound effect in MDR-1 deficient dogs. Phenothiazines have been shown to have an inhibitory effect on P-glycoprotein and may thus alter the uptake of other drugs into the brain. Acepromazine seems to have a more profound sedative effect in these dogs (Mealey, 2006). The pharmacogenomics of this phenomenon is discussed in Chapter 50.

The rate at which drugs cross the BBB is governed by the above activities and also the physicochemical properties of the drug itself. Molecular size, lipid solubility, hydrogen bond donor sites, and external oxygen and nitrogen affect the passage across the BBB. Polar molecules are not able to cross the BBB, so the drug needs to be present in an unionized form in order to get into the brain. Lipid solubility is measured in a number of ways but one of the most common is to measure the octanol/buffer partition coefficient and express this as a log value, usually given as Log P. Molecules that are less likely to penetrate the BBB would have a molecular weight >450 g/mol, a Log P >4, >5 hydrogen bond donors, and the sum of nitrogen and oxygen atoms >10. On the other end of the scale, molecules with low Log P values (<2) also have low penetrance, leading to a sigmoid-shaped curve when Log P is plotted against brain uptake. This can be illustrated by the pharmacodynamics of morphine (Log P = 0.1), alfentanil (Log P = 2.1), and sufentanil (Log P = 3.24), where the peak effects of the drugs are approximately at 2–3 hours, 1 minute, and 6 minutes, respectively (Lotsch, 2005).

Epidural Barrier

Drugs administered into the epidural space must diffuse through the dural membranes in order to reach the spinal cord where they might have an effect (Bernards and Hill, 1990, 1991). This diffusion is dependent on many of the usual factors (concentration gradient, molecular size, polarity, lipid solubility, and distance) but the same sigmoid effect of lipid solubility is seen here as well (Bernards and Hill, 1992). This is demonstrated in Figure 9.5 where Log P is plotted against meningeal permeability measured in vitro. Epidural fat plays a role in that very lipid-soluble drugs tend to get absorbed here thus limiting their uptake into the spinal cord. The main meningeal barrier to diffusion is the pia–arachnoid membrane with its complex mix of aqueous fluids (CSF and extracellular fluid) and lipid membranes. The distance effect is illustrated in Figure 9.6 where the time to onset is plotted against depth across a number of species following intrathecal administration (Yaksh, 2005).

Principles of Anesthesiology

Anesthesiology is defined as the art and science of administration of anesthesia. The term also describes a clinical specialty of medicine (including veterinary medicine) that emerged during the early 1900s when a few physicians began devoting full time to the clinical administration of anesthetics. Anesthesiology was officially recognized as an organized specialty in medicine with the establishment in 1938 of a peer-certifying body of physicians, the American Board of Anesthesiologists (ABA). Initially, the ABA was an affiliate board of the American Board of Surgery but in 1941 it became an independent board. In addition, in 1940, a section of anesthesiology was formed within the American Medical Association. In 1975, the American College of Veterinary Anesthesiologists was officially recognized by the American Veterinary Medical Association as the body to certify veterinarians as specialists in veterinary anesthesia. Broader summaries of the development of anesthesiology are available elsewhere (Smithcors, 1971; Weaver, 1988; Larson, 2005; Weaver and Hall, 2005; Steffey, 2014). The central role of the anesthetist is: (i) to apply methods to minimize or eliminate pain, relax muscles, and facilitate patient restraint during surgical, obstetrical, and other medical, diagnostic, and therapeutic procedures; and (ii) to monitor and support life functions in patients during the operative period as well as in critically ill, injured, or otherwise seriously ill patients. The skills and knowledge that have developed in the field have extended the clinical practice of anesthesiology into intensive care, cardiac and pulmonary resuscitation, and the control of pain problems unrelated to surgery. The word *anesthesia* is derived from the Greek for “insensible” or “without feeling.” The word does not necessarily imply loss of consciousness.

Source: Drawn from Yaksh TL, Spinal Analgesic Mechanisms. In *Pain 2005—An Updated Review.* International Association for the Study of Pain, 909 NE 43rd St, Suite 306, Seattle, WA 98105-6020.

In the realm of veterinary anesthesiology, anesthesia and anesthetics are used for a variety of reasons (Table 9.4).

Anesthetic Use

Perception of Noxious Stimuli (Pain)

Prevention of the perception of a noxious stimulus during surgery is the primary justification for anesthesia. A noxious stimulus is defined as a stimulus that is potentially damaging to body tissue. Nociception has no emotional or perceptional connotation. Pain is an unpleasant sensory and emotional experience; it is a perception, not a physical entity. The perception of pain depends on a functioning cerebral cortex. The concept of pain includes several interdependent dimensions: the sensory/discriminative and motivational/affective.

Table 9.4 Use of anesthetics in animals

- Elimination of sensitivity to noxious stimuli
- Humane restraint (e.g., protect animal, facilitate diagnostic or surgical procedure)
- Technical efficiency (e.g., protect personnel, facilitate diagnostic or surgical procedure)
- Specific biomedical research tool (e.g., sleep time)
- Control convulsions
- Euthanasia

It is not the intent to sidetrack here into semantic issues or to belabor what are, to some, fine points but it is necessary for completeness to stress that contemporary reasoning holds that pain is a subjective response in conscious human beings. When considering “pain” in animals, it is important to recognize that our knowledge of pain in animals is largely inferential. We approach the subject with “the tacit assumption…that stimuli are noxious and strong enough to give rise to the perception of pain in animals if the stimuli are detected as pain by human beings, if they at least approach or exceed tissue damaging proportion and if they produce escape behavior in animals" (Kitchell and Erickson, 1983).

Classical approach to mechanisms of pain: Before further discussion of methods by which insensitivity is produced, it is helpful to briefly review the mechanisms whereby an individual becomes aware of and reacts to a noxious stimulus (Figure 9.7). This inclusion here is justified on the basis that knowledge of these mechanisms offers the clinician targets for single or multiple attacks in an attempt to abolish or minimize pain.

Acute pain that is provoked by disease or injury (planned or unplanned) is the net effect of many interacting and complex anatomic paths and physiological mechanisms. The stimulus excites a specialized receptor organ, the nociceptor. Nociceptors are distributed throughout the body but are frequently grouped as somatic (cutaneous, muscle, bone, joint, fascia) or visceral. Nociceptors are located at the termination of free nerve endings of small poorly myelinated or nonmyelinated A-delta and C afferent nerves. The nociceptors transduce the stimuli into nociceptive impulses that are transmitted to the CNS (see Section Transduction). Impulses that originate from areas below the head are transmitted via fibers that synapse with interneurons or second-order neurons in the dorsal horn of the spinal cord. Impulses from the head travel via fibers within the cranial nerves to the medulla, where they synapse with neurons in the trigeminal nuclei (medullary dorsal horn). In the spinal cord, the signal is subjected to a variety of potential modulating influences in the dorsal horn. For a long time the dorsal horn was considered to perform simply as a relay station. More recent evidence indicates it contains an incredibly complex circuitry and rich biochemistry that permits not only reception and transmission of nociceptive impulses but also a large degree of signal processing. After being subjected to these modulating influences, some of the impulses may then stimulate somatomotor and preganglionic sympathetic neurons and provoke nocifensive reflex responses. Nociceptive impulses also activate other neurons making up the ascending systems that pass to the brain stem and brain. Supraspinal systems that are probably involved in processing nociceptive information to progressively higher levels of awareness include the reticular formation, limbic system, hypothalamus, thalamus, and cortex.

Activation of the reticular formation results in abrupt awakening, diffuse alertness, and initiation of protective homeostatic responses. In turn, affective (emotional) alertness is obtained through cortical arousal. The animal is now fully knowledgeable regarding the cause and strength of the noxious stimulus and its relationship to the environment. The animal in turn reacts with a coordinated response.

The above simplified description encompasses the processes associated with acute pain that might be caused by a surgical incision into normal tissue. However, chronic pain states can involve changes in activity at any part of the nociceptive system. As indicated above, the inflammatory mediators released into the tissues will sensitize the nociceptors and may lead to alteration in the receptors expressed (e.g., TRPV-1). In the spinal cord a barrage of input from the nociceptors can lead to changes in the glutamate receptors with activation of the NMDA receptors and an enhancement of the incoming signals. In addition to this, the glial cells may also be activated

and both amplify the signal and sensitize the neurons to further input. It is thought that phenomena such as phantom limb pain and the chronic pain associated with interstitial cystitis are largely mediated by changes in the dorsal horn. The central processing of pain in the brain also provides on-going modifiers to the incoming signals. It is well established that the system that provides descending inhibition of nociception can be so effective that it can prevent the animal from feeling pain associated with acute injury but the effect on chronic pain is less understood. Stress can stimulate both the descending inhibitory and facilitatory pathways and it seems that acute stress may increase inhibition whereas chronic stress facilitates nociceptive input. These elaborate mechanisms allow us to use drugs in chronic pain that may not be analgesics in their own right but may affect part of these neurochemical events to decrease pain. Examples include minocycline to block glial activation and gabapentin and tricyclic antidepressants to decrease descending facilitation.

For more detailed information the reader is referred elsewhere (Fishman et al., 2010; Fox, 2010; McMahon and Kolzenburg, 2013).

Immobility

Although the primary reason for anesthetic delivery is to render the animal insensible to pain, restraint and technical efficiency are also long-recognized important considerations. Although viewed as an extreme in approach today, Alexandre Liautord, a Frenchman, noted in his 1892 *Manual of Operative Veterinary Surgery:* "In veterinary surgery, the indication for anesthesia has not, to the same extent as in human, the avoidance of pain in the patient for its object, and though the duties of the veterinarian include that of avoiding the infliction of *unnecessary* pain as much as possible, the administration of anesthetic compounds aims principally to facilitate the performance of the operation for its own sake, by depriving the patient of the power of obstructing, and perhaps even frustrating its execution, to his own detriment, by the violence of his struggles, and the persistency of his resistance. To prevent these, with their disastrous consequences, is the prime motive in the induction of the anesthetic state" (quoted in Smithcors, 1971). More in keeping with contemporary thought are the words of George H. Dadd written in 1854 in *The Modern Horse Doctor:* "We recommend that, in all operations of this kind, the subject be etherized, not only in view of preventing pain, but that we may, in the absence of all struggling on the part of our patient, perform the operation satisfactorily, and in much less time after etherization has taken place than otherwise. So soon as the patient is under the influence of that valuable agent, we have nothing to fear from his struggles, provided we have the assistance of one experienced to administer it" (quoted in Smithcors, 1971). Many of these same clinical principles can and should also be applied directly to the research environment.

Table 9.5 Routes by which anesthetic or anesthetic adjuvant drugs are administered in animals

1. Topical
    a) Cutaneous
    b) Mucous membrane
2. Injection
    a) Intravenous
    b) Subcutaneous
    c) Intramuscular
    d) Intraperitoneal
    e) Intraosseous
3. Gastrointestinal tract
    a) Oral
    b) Rectal
4. Respiratory system (e.g., inhalation)

Anesthesia Classified

Anesthesia is produced by both chemical (i.e., drugs) and physical (e.g., sensory nerve destruction) means. Anesthetic drugs are frequently classified according to their route of administration (Table 9.5). Some drugs are only suited for common delivery via one route (e.g., the inhalation anesthetics), while many of the injectable agents may be administered in a variety of different manners depending on the drug and the desired endpoint of effect.

Local and Regional Anesthesia

Anesthetics are also classified according to the region of the body influenced (Table 9.6). For example, a local anesthetic is administered to desensitize a localized or regional area of the body. It is deposited in close proximity to a nerve membrane, causing nerve conduction

Table 9.6 Techniques of anesthesia based on extent of loss of sensation

1. Local/regional: drugs placed in close proximity to nerve membranes, causing conduction block
    a) Topical or surface
    b) Area infiltration
        i. Subdermal
        ii. Intravenous regional
    c) Perineural (i.e., nerve trunk)
    d) Peridural (i.e., epidural or caudal)
    e) Subarachnoid (i.e., spinal)
2. General anesthesia: state of controlled, reversible CNS depression (including unconsciousness) produced by one or multiple drugs
    a) Injectable
    b) Inhalation
    c) Balanced

blockade. This may be used in the conscious patient and is widely used in large animal practice to allow procedures to be done in the standing patient. Increasingly, local anesthetics are being used in conjunction with general anesthesia or heavy sedation to block the nociceptive input from the surgical site.

General Anesthesia

General anesthesia is a condition induced by pharmacological or other means that results in controlled, reversible CNS depression. It is true that some drugs in the process of producing anesthesia cause excessive stimulation and activity in the brain, but all anesthetic agents ultimately reduce and stop electrical activity in the brain and decrease brain oxygen consumption. On this basis, it is proper to characterize anesthetic agents as CNS depressants.

There is no consensus about the essential elements that comprise the behavioral state that we term *general anesthesia*. Further complication is added by trying to match human and animal studies. For example, sedation is sometimes defined as loss of appropriate responsiveness to verbal command – relatively easy for use with human subjects, more difficult or not possible with animals. For this introductory overview and further discussion, basic elements of general anesthesia will, in addition to reversibility, include absence of awareness (unconsciousness), no recall of events at the conscious level (amnesia), conscious insensitivity to pain (analgesia), and muscle relaxation and diminished motor response to noxious stimulation (immobility). The importance of minimal autonomic nervous system response to noxious stimulation has also been emphasized by some in clinical applications.

General anesthesia has traditionally been considered a dose-related continuum of a series of events passing into each other (Figure 9.8), from alert wakefulness through lethargy and drowsiness (sedation), unconsciousness (with and without somatic and visceral response to external stimuli), coma, and death. The wakefulness to coma series implies progressive loss of higher CNS (cortical) function followed by depression of brain stem functions. While portions of this scheme have been challenged, its use remains, in general, acceptable and offers a convenient method to set the stage for further discussion of introductory level understanding or principles of general anesthesia.

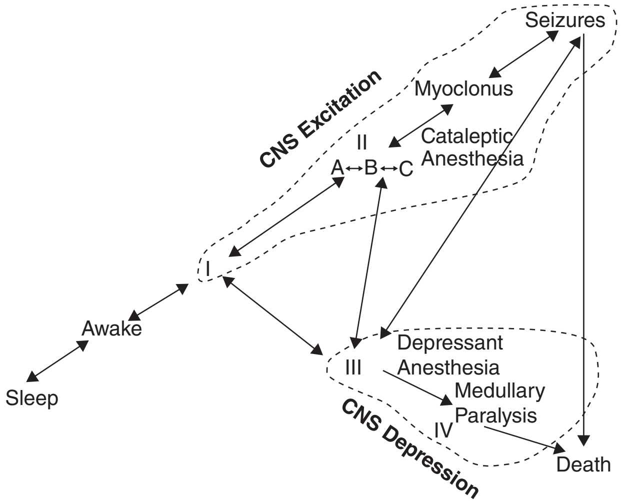

Figure 9.8 Schematic representation of the stages of anesthesia according to Winters et al. (1972) and Winters (1976). The schematic has been modified slightly from its original description. I–IV refer to the classic stages of anesthesia.

Techniques of general anesthesia: General anesthesia is pharmacologically induced and maintained in animals via one of two general methods. The oldest approach, which is still used in certain animal applications, is the single-agent technique. With this technique, an agent such as pentobarbital, thiopental, or ketamine is administered at sufficient dose to provide the complete spectrum of characteristics of general anesthesia. This method is simple but may be more life threatening, especially under adverse circumstances, including animal ill health. Because *all* anesthetic agents have some undesirable effects when used alone (the LD_{50}/ED_{50} is commonly no more than 2–4), modern anesthetic practice most commonly involves the use of combinations of drugs. With more modern technique, multiple drugs are used, at lower doses than would be needed if used alone, with each drug being used for a specific purpose (amnesia, immobility, analgesia, unconsciousness). This technique is known as *balanced anesthesia* and was originally conceived to encompass techniques that used a drug for each component. This might have been an inhalant for unconsciousness, a benzodiazepine for amnesia, an opioid for analgesia, and a neuromuscular blocking drug for immobility. In modern usage *balanced anesthesia* is often applied to any technique using more than one class of drug as part of an anesthetic technique. The ultimate intent is to take advantage of the desirable features of selected drugs while minimizing their potential for harmful depression of homeostatic mechanisms. This technique is especially advantageous when used with physiologically compromised individuals. Another disadvantage of using single drugs for anesthesia is that they may provide unconsciousness and immobility but may leave the nociceptive system intact such that the surgical procedure will still enhance central facilitation of nociceptive input. This sets the animal up for a worse pain experience in the postoperative period and possibly long-term pain. Although this phenomenon was recognized in the 1920s, more recent knowledge of the mechanisms involved has led to a resurgence of approaches, applied in the perioperative period, to decrease nociceptive input into the CNS. These include more extensive use of pre- and intraoperative analgesics and local anesthetic local and/or regional nerve blocks. A sound understanding of the effects of each addition to the basic approach is needed in order to avoid undesirable drug actions and/or toxicities.

Mechanism of action causing general anesthesia: There have been many attempts to explain the mechanism of general anesthesia at a molecular level. Initially this was aimed at having a unified theory to explain the action of all anesthetics but is now clear that there is a significant difference between most of the injectable and the inhaled anesthetics. Drugs like thiopental, propofol, etomidate, and alfaxalone produce their effects at lower concentrations (nM to μM range) than the inhaled anesthetics that need mM concentrations for their action. It is now known that these injectable anesthetics have their major effect through the $GABA_A$ channel by enhancing the effect of GABA. However, it is also recognized that there are many versions of this receptor, depending on the incorporated subunits, and that specific versions of the receptor may be predominant in some areas of the brain and spinal cord providing a possible basis for species differences in the effects of some of these drugs. The cyclohexanones (ketamine, tiletamine, phencyclidine) are NMDA receptor antagonists and block the actions of the excitatory neurotransmitter glutamate. A unified theory will also have to account for the fact that many of these anesthetics affect the righting reflex, immobility, memory, and nociception, all of which involve different neurotransmitters and receptors. For example, using mice with mutations in the α_1 subunit of $GABA_A$ an effect was demonstrated on the righting reflex while the immobilizing and amnestic effects of isoflurane were unaffected (Sonner et al., 2007). In addition, the diverse chemical structures of inhaled anesthetic agents also pose a problem in arriving at a common theory of action. The inhaled anesthetic drugs range from inert gases such as xenon and relatively simple inorganic (nitrous oxide, carbon dioxide) to organic (isoflurane, sevoflurane) compounds.

For more than a century, two concepts have dominated thinking about the mechanism of action of inhaled anesthetics. Since a wide range of structurally unrelated agents caused anesthesia, Claude Bernard postulated that all of them did so by a common mechanism, the *unitary theory of narcosis* (Leake, 1971). A striking physiochemical characteristic of inhalation anesthetic drugs is their lipid solubility – a physical property shown to correlate best with anesthetic potency. This correlation is commonly referred to as the *Meyer–Overton rule* after the two individuals who independently (in 1899 and 1901, respectively) noted that the potency of anesthetics increased directly in proportion to their partition coefficient between olive oil and water (i.e., the concentration ratio of the agent in oil and water at equilibrium). However, lipid solubility is not the only factor because there are many compounds with lipid solubilities similar to the inhaled anesthetics that do not have any anesthetic affect. Analysis of steric and electrostatic properties of the halogenated inhaled anesthetic drugs shows a structural correlation with potency (Sewell and Sear, 2006) and it is possible that such structural analyses may lead to the development of new anesthetics (Ebalunode et al., 2009). Because inhalation anesthetic molecules are hydrophobic and therefore distribute to sites in which they are removed from aqueous environments, and because of the close correlation between potency and lipophilicity, it was theorized that these anesthetics acted in the cell membrane lipid layer and this idea is still being pursued (Weinrich and Worcester, 2013). The inhalant anesthetics cause immobility through an action in the spinal cord and this is most likely to be in the ventral horn (Kim et al., 2007). In an analysis of the putative receptor mechanisms that could be involved in inhalant immobility, Eger et al. (Eger et al., 2008) eliminate all the commonly suggested receptors except the sodium channel and an, as yet, undiscovered potassium channel. A large part of their argument focuses on the fact that, while many of the inhalant anesthetics have actions at different receptors, the activities are not consistent enough at any single receptor to explain immobility.

Basics of Clinical Anesthesia

A favorable anesthetic course begins with a good plan – a plan based on sound pharmacological and physiological principles. There is no rigid format. *No anesthetic technique is unequivocally the best for all animals under all circumstances.* Each plan is adapted to prevailing circumstances. Accordingly, appropriate anesthetic management requires a broad understanding of the physiology of bodily life support systems (e.g., respiratory, circulatory, central and autonomic nervous systems), the pathology and pathophysiology of the condition(s) necessitating anesthesia and surgery, the pharmacology and principles and techniques of administration of anesthetic and adjuvant drugs, and monitoring and support of vital organ function. The rationale that underlies the selection of an appropriate anesthetic protocol is outlined in Table 9.7.

Drug selection for anesthetic management is accomplished by considering the pharmacological requirements for the individual case, reviewing and selecting major drug classes that are appropriate for the specific needs, and then reviewing characteristics and selecting the specific drug(s) within the desired drug class(es). Frequently, the best drug and technique are those with which

Table 9.7 Considerations in the selection of appropriate anesthetic protocol and drugs

1. Animal characteristics (e.g., species, age, physical status)
2. Capabilities and confidence of anesthetist
3. Capabilities of surgeon and surgical requirements
4. Available drugs, facilities, and ancillary personnel
5. Wishes of client

the clinician is most experienced; that is, there is an art to the clinical administration of potent, life-threatening drugs such as those used in anesthetic management.

Drugs used in anesthetic management can be conveniently classified according to time frame of use: the preanesthetic, perianesthetic, and immediate postanesthetic periods.

Preanesthetic Period

Drugs are usually administered to animals (usually 15–45 minutes) before induction of general anesthesia. The primary aims of preanesthetic medication are to calm the animal, facilitate handling, and relieve preoperative pain. These along with secondary goals are listed in Table 9.8. Unfortunately, preanesthetic medication is not without its complications, which also must be considered in formulating the anesthetic management plan (Table 9.9). The concurrent use of two or three drugs is usually required to accomplish the desired preanesthetic conditions in the patient. These are selected from a variety of major drug classes (Table 9.10). The extent of drug combinations advocated by individuals attests to the variety of circumstances commonly encountered clinically and to the lack of agreement on optimal drug effects.

Tranquilizer-sedatives: Tranquilizers (ataractics or neuroleptics) are frequently administered to animals to produce a calming effect, that is tractability or "chemical restraint." This group of drugs includes the phenothiazine, the butyrophenone, and the benzodiazepine subclasses. They are frequently used in combination with other preanesthetic drugs (e.g., opioids), because lower doses can be used than would be the case if each drug were used alone and the degree of sedation accomplished by the drug combination is often potentiated without causing further severe circulatory and respiratory depression.

Table 9.8 Goals for preanesthetic medication

1. Alleviate or minimize pain
2. Allay apprehension
3. Facilitate handling
4. Minimize undesirable reflex autonomic nervous system activity
    a) Parasympathetic
        i. Vagal nerve
        ii. Secretions: salivary, bronchial
    b) Sympathetic
        i. Arrhythmias
        ii. Arterial blood pressure alterations
5. Supplement general anesthesia
    a) Add to level of analgesia, sedation
    b) Reduce anesthetic requirement
6. Minimize undesirable postanesthetic recovery complications
7. Prevent infection
8. Continue treatment of intercurrent disease

Table 9.9 Complications of preanesthetic medication

1. Depressed vital organ function
    a) Direct effects
    b) Interaction with anesthetic and other adjuvant drugs
2. Antianalgesia
3. Prolonged sedation influencing recovery from anesthesia
    a) Prolonged recumbency
    b) Ataxia

The phenothiazines have been used extensively for decades. They are relatively potent and produce moderately reliable tranquilization. They have antiarrhythmic, antihistaminic, and antiemetic effects that may be

Table 9.10 Major classes of drugs (and specific drug examples) commonly considered for preanesthetic medication

1. Tranquilizer-sedative
    a) Acepromazine
    b) Azaperone
    c) Benzodiazepines
        i. Diazepam
        ii. Midazolam
2. Hypnotic-sedative
    a) Pentobarbital
    b) Chloral hydrate
3. Opioid
    a) Agonist
        i. Morphine
        ii. Meperidine
    b) Agonist-antagonist
        i. Butorphanol
    c) Partial agonist
        i. Buprenorphine
4. α_2-adrenergic agonist
    a) Xylazine
    b) Detomidine
    c) Romifidine
    d) Medetomidine
    e) Dexmedetomidine
5. Dissociative
    a) Ketamine
6. Commercially prepared combinations of sedating drugs
    a) Telazol (tiletamine + zolazepam)
7. Parasympatholytic
    a) Atropine
    b) Glycopyrrolate

particularly desirable. The α_1-adrenergic blocking action of the phenothiazines is likely to be of special concern in some patients because it may result in arterial hypotension.

The butyrophenones also have α_1-adrenergic blocking activity, but appear to be less potent in this regard. Largely on the basis of cost and the lack of broad-based, clear advantages, the butyrophenones are less frequently used for anesthetic management of domestic veterinary patients but are increasingly used in zoo and wildlife settings.

The sedative effects of benzodiazepines, in otherwise healthy animals, are quite variable across animal species commonly encountered in veterinary practice. Consequently, these drugs are commonly used as adjuncts to other preanesthetic drugs in small animals but may be used alone in small ruminants. Pain and occasional erratic absorption after intramuscular injection are characteristic of some benzodiazepines (e.g., diazepam). Sedation caused by benzodiazepines can be reliably reversed by a specific antagonist, at least in some species.

Hypnotic-sedatives: Drugs of this class, including the barbiturates and chloral hydrate, cause a dose-dependent spectrum of CNS depression, sedation, sleep, anesthesia, coma, and death. They produce minimal ventilatory and circulatory depression in sedative doses. Disadvantages of their use include a lack of analgesia and the absence of specific antagonists. Use of drugs from this class have largely been replaced in the preanesthetic period by the α_2-adrenergic agonist drugs.

α_2-Adrenergic drugs: Drugs, such as xylazine, romifidine, and dexmedetomidine, cause dose-related sedation and analgesia. They are widely used across species lines singly and in combination, especially with opioids and dissociative agents. Bradycardia, mild arterial hypertension followed by more prolonged hypotension, hyperglycemia, and increased urine volume are commonly attendant effects. Direct antagonists of varying purity and effectiveness are now available and a peripherally acting antagonist (does not cross the BBB) is being examined with the potential to mitigate most of the cardiovascular effects of these drugs (Honkavaara et al., 2011).

Opioids: Potent analgesia, sedation, and the absence of direct myocardial depression are important advantages of the use of opioids in the preanesthetic period. Patients with preexisting preoperative pain or who will require painful diagnostic or therapeutic procedures before anesthetic induction are likely candidates for opioid preanesthetic medication. Opioid premedication is also appropriate prior to anesthetic management techniques that use opioids as a predominant component (i.e., a balanced technique, see Section General Anesthesia). The main adverse effect of opioids when used prior to anesthesia is the depression of medullary ventilatory control centers resulting in decreased responsiveness to carbon dioxide and in turn hypoventilation. Opioids commonly induce a vagotonic effect so heart rate may also be decreased to variable degrees depending on agent, dose, and animal species. In some species (e.g., the dog) opioids commonly cause CNS sedation, while in others (e.g., the horse) excitement or CNS arousal are predominant concerns. Opioid-induced vomition in some species (e.g., dog) may be wanted (e.g., a newly presented patient with a full stomach requiring anesthesia for a diagnostic or minor surgical procedure) or unwanted (e.g., risk of pulmonary aspiration of vomitus in elderly or depressed patients). They also decrease intestinal propulsive and ruminal activity.

Dissociative drugs: Drugs such as ketamine and tiletamine reliably cause a state of somatic analgesia and sedation in some species (e.g., cat) and may be of benefit in special clinical situations (e.g., highly fractious animals under conditions of limited management choices). Their relatively wide margin of safety in otherwise healthy animals is of special benefit under conditions of limited patient control or understanding of its condition. Ketamine is being used in various combinations in horses and cattle to “stun” the animal to allow brief noxious procedures such as castration or dehorning.

The most prominent disadvantage of their use is that, depending on dose, this class of drugs may cause CNS arousal in some species (e.g., horse) leading to animal excitement or frank convulsions.

Drug combinations: Sometimes, drug combinations are marketed to provide ready access to clinical benefits of two drugs while attempting to minimize their individual disadvantages. For example, Telazol® is a combination of tiletamine, a dissociative agent, and zolazepam, a benzodiazepine tranquilizer-sedative. The combination improves the reliability of the sedative properties of either drug used alone without adding extensively to further vital organ depression (e.g., cardiopulmonary depression). However, as a consequence of the fixed combination, a prolonged duration of effect may be an unwanted result.

Parasympatholytic (anticholinergic) drugs: The most common reason for administering drugs such as atropine or the more potent, longer-acting glycopyrrolate before induction of general anesthesia is to reduce upper-airway and salivary secretions (antisialagogue effect) and counteract reflex bradycardia occurring with, for example, concurrent opioid use or certain surgical manipulations (e.g., ocular).

In years past, it was routine to use anticholinergics as part of the premedication scheme. Although modern inhalation anesthetics tend to decrease airway secretions, it is very common in clinical management of small companion animals to administer opioids as part of anesthetic premedication so anticholinergics may still be considered beneficial in preventing bradycardia. Some argue that heightened vagal tone is best treated just prior to its anticipated occurrence or at first sign of its presence. Sparing use of anticholinergic drugs reduces the risk of other unwanted effects such as tachycardia or reduced gastrointestinal motility. Avoidance of gastrointestinal stasis is of special importance in herbivorous animals, for whom preanesthetic gastrointestinal emptying is almost never desired or accomplished. Mydriasis is another effect (e.g., of atropine) that is often undesirable because it confounds interpretation of some clinical signs of anesthesia and/or exposes the patient to potential retinal damage in some uncontrolled postanesthetic circumstances.

Anesthetic Period

The administration of anesthesia requires a combination of knowledge, skill, and ingenuity. The anesthetic drugs selected and their doses and methods of delivery will largely depend on the animal, the facilities available, and the skill of the individual who will administer them.

General anesthetics are usually given by inhalation or injection; on rare occasions anesthetic drugs may be given orally or per rectum. More specific information on anesthetic delivery is given later in this volume and in cited references (Tranquilli et al., 2006; Dorsch and Dorsch, 2007; Clarke et al., 2014).

Drugs of several classes of injectable agents (Table 9.11) are commonly used for general anesthesia. These are preferably given intravenously (IV); however, because of the varied circumstances associated with clinical conditions in veterinary medicine, the intramuscular (IM) route is also widely used. The IV route is the preferred means of inducing general anesthesia because anesthetic induction with the loss or reduction of many of the patient's life-protecting reflexes is consistently the most crucial maneuver in managing general anesthesia. The IV administration permits incremental dosing and thus titration of the level of anesthetic to a desired end point. This technique is often desired, especially in critically ill patients or in unfamiliar circumstances, because of the likelihood of unpredictable animal responses to a "routine" dose of drug. Drugs of a single class are used alone or in combination with other drugs listed in Table 9.11 (e.g., inhalation anesthetics and neuromuscular blocking drugs) to achieve suitable anesthetic conditions. Many of the drugs from the classes listed in Table 9.11 are also used at lower doses for preanesthetic medication (Table 9.10).

Table 9.11 Major classes of CNS drugs (and examples) commonly considered for general anesthesia

1. Hypnotic-sedatives
    a) Ultrashort-acting (i.e., thiopental)
    b) Short-acting (e.g., pentobarbital)
2. Dissociative
    a) Ketamine
3. Opioid
    a) Morphine
    b) Oxymorphone
    c) Fentanyl
    d) Alfentanil
4. Drug combinations (i.e., Telazol®)
5. Others
    a) Guaifenesin
    b) Propofol
    c) Etomidate
    d) Alfaxalone
6. Tranquilizer-sedatives[a]
    a) Benzodiazepines
        i. Diazepam
        ii. Midazolam

[a] Use as an anesthetic adjuvant in conjunction with others on the list, e.g., opioids or ketamine.

The thiobarbiturates are no longer available in the United States but are still used extensively in other countries. Propofol is used extensively in small animals and the dissociative drugs are used in the most species with almost universal application to anesthetic induction in horses. Alfaxalone has been reintroduced in a new formulation in cyclodextrin and is licensed for use in dogs and cats.

Opioids in large doses are the basis for balanced anesthetic techniques for human patients, especially those patients with circulatory system instability or those undergoing cardiac surgery. This method is also applicable to some veterinary patients (e.g., dogs) and is presently used to varying degrees. An important point to keep in mind is that opioids, even in large doses, do not predictably produce unconsciousness, so other drugs are used concurrently to accomplish the individualized goals of general anesthesia. Also, some animal species (e.g., horses) are excited by even moderate (by comparison to other species, e.g., dogs) opioid doses. The reader should consult Chapter 13 for further discussion.

Immediate Postanesthetic Period

The immediate postanesthetic period is also known as the *anesthetic recovery period*. It begins with the discontinuation of the administration of anesthetic drugs. Recovery of healthy animals from routine anesthetic techniques is usually, but not always, uneventful and routine. Circumstances such as compromised physical status and unfamiliar anesthetic techniques heighten the likelihood of recovery problems. The immediate goal of this

Table 9.12 Hazards of the immediate postanesthetic period

1. Circulatory system complications
   a) Arterial hypotension
   b) Arterial hypertension
   c) Cardiac dysrhythmias
2. Respiratory system complications
   a) Hypoxemia
   b) Hypercapnia (hypoventilation)
3. Pain
4. Emergence excitement (physical trauma)
5. Hyperthermia/hypothermia
6. Vomiting
7. Delayed awakening

period is the rapid return of the patient's independent, uncompromised ability to maintain normal respiratory and circulatory systems function and to return sensory and motor abilities to preanesthetic levels as soon as possible. Despite this overriding philosophy, when the needs of different species and circumstances are considered, the actual broad plan is less clear. For example, most of the contemporary inhalation anesthetics do not have potent or persistent analgesic properties at alveolar concentrations associated with awakening. The sooner a patient recovers following surgery, the sooner there is potential for pain and discomfort for the patient. Consequently, the question arises, is it better for a patient to awaken quickly following surgery and then receive, as needed, analgesic drugs, or is it more desirable and beneficial for the patient to receive analgesic drugs toward the end of the anesthetic period and as a result have a slower recovery from general anesthesia and transition to sensation? The same therapeutic dilemma applies to the patient who may emerge from anesthesia excited and risk a particularly "stormy" recovery with attendant physical injury. The various combinations of drugs used in anesthetic management coupled with unique species characteristics make it impossible to describe here all of the patterns of recovery that occur and appropriate therapeutic schemes. In the end, individualized therapy is the most desirable plan.

Hazards of the recovery period that may require therapeutic intervention are listed in Table 9.12.

Evaluation of the Response to Anesthesia

Since very early in the history of general anesthesia, attempts have been made to correlate observations of the effects of anesthetics with "depth" of anesthesia. To be able to define the depth of anesthesia is important for a number of reasons. For example, too little or too much anesthesia is a threat to life. Consequently, if one can determine the magnitude of anesthesia with reasonable accuracy, patient safety is improved and optimal operating conditions are facilitated for the health care providers. Furthermore, specific guidelines help the novice anesthetist provide appropriate anesthetic conditions. Finally, in investigative circumstances an accurate means for describing and comparing anesthetic levels within or between studies is essential so that we may account for the effects of the anesthetic in our overall understanding versus other variables that may be operant and of interest at the time of study. It would be very helpful to be able to precisely define the depth of anesthesia in every animal from moment to moment regardless of the anesthetic technique. Unfortunately, this is presently not possible, so we rely on estimates.

More than 80 years ago, Guedel (Guedel, 1920, 1927) published his classic description of the four stages of anesthesia. The traditional classification is based on a progressive depression of a continuum of CNS function. Guedel extended the descriptions of earlier workers such as Plomley (Plomley, 1847) and Snow (Snow, 1847) to divide the state of anesthesia into distinct "packages," each correlating with a particular set of physiological responses or reflexes, that is clinical signs. The organizational scheme includes four stages of anesthesia and subdivides the third stage into four strata (i.e., planes) (see earlier editions of this text for a broader description). Guedel's system has been prominent in pharmacology texts (including earlier editions of this text) and anesthesia texts for more than six decades. The concept is included here in only abbreviated form because with newer drugs and changes in clinical practice its importance in the discussion of fundamental principles of anesthesia is limited.

The classic signs and stages are partly recognizable with many general anesthetics (e.g., the barbiturates), but they are incomplete or are obscured when using modern anesthetics (e.g., ketamine) and/or techniques. It is important to remember that Guedel's description was based on his observation of the actions of diethyl ether administered to otherwise unmedicated human patients who were breathing spontaneously. This is a situation far different from contemporary clinical practice (including veterinary), in which controlled mechanical ventilation is common and newer and multiple anesthetic and adjuvant drugs are an important part of the anesthetic plan. There are unique differences in the way different species react to conditions of general anesthesia that also must be taken into consideration. Because of diethyl ether's characteristics and the methods of delivery, the onset and "deepening" of anesthesia were slow. This situation facilitated a slow (relative to today's standards) unfolding. In addition, numerous physiological responses to anesthetics that are widely monitored today (Table 9.13) are not included in the classic description.

With the emergence of anesthetics such as ketamine and enflurane (absent from veterinary practice for more

   e) Vocalizing[a]
   f) Salivating
   g) Sweating
   h) Urine flow

[a]Moderate or [b]high specificity in assessment of anesthetic depth for various animal species and anesthetic agents.

than two decades), the concept that all anesthetics are depressants required reconsideration. Winters et al. (1967) proposed replacement of the classic, unidirectional schema (Figure 9.9) of CNS excitation and depression with a new schema that included a description of progressive states of both CNS depression and excitation (Figure 9.10). The new schema recognized bidirectional influences of drugs acting on the CNS and was based on results of electrophysiological studies of anesthetic, excitatory, hallucinogenic, and convulsive agents in cats (Winters et al., 1967; Winters et al., 1972; Winters, 1976).

Guedel's scheme also does not take into consideration the modifying influences of such things as duration of anesthesia (Dunlop et al., 1987; Steffey et al., 1987a, 1987b) or varying magnitudes of surgical stimulus intensity on the signs of anesthesia (Eger et al., 1972; Steffey, 1983). In modern clinical anesthetic practice it is recognized that no single observation is always reliable as a sign indicating a specific magnitude of anesthesia. Accordingly, anesthetists are encouraged to develop a basic background knowledge of both the individual to be anesthetized and the selected drugs. Current advice for anesthetic management under clinical conditions is to use an initial anesthetic loading dose just necessary

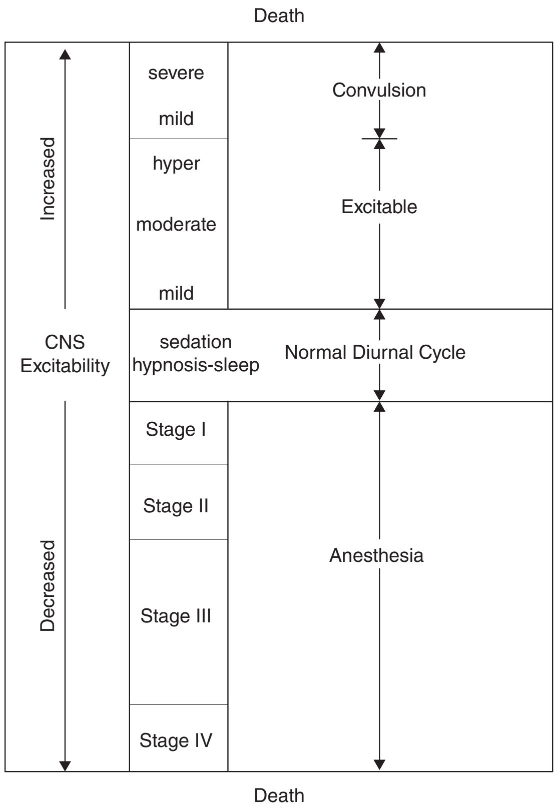

Figure 9.9 The classic unidimensional schema of CNS excitation and depression. Source: Adapted from Winters, 1976.

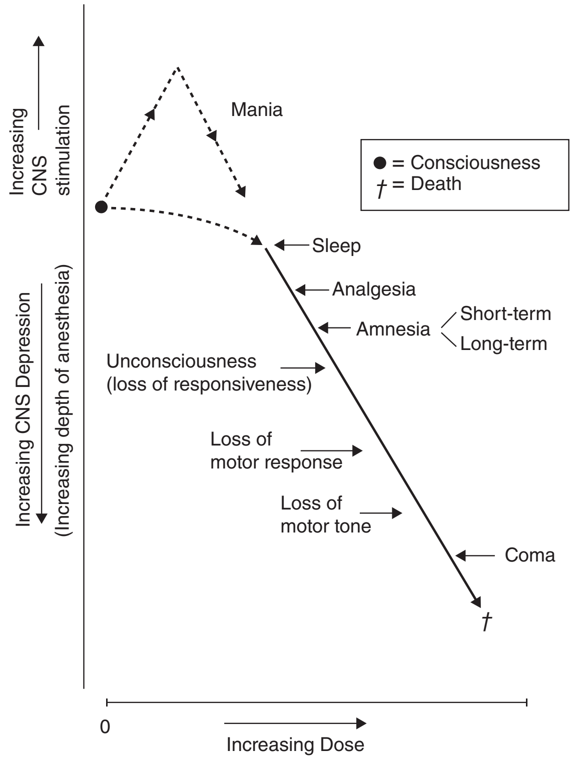

Figure 9.10 The anesthetic continuum as viewed clinically in a healthy subject.

to suppress purposeful movement and to observe all signs possible in each patient (Table 9.13) and then to manipulate further anesthetic dose in relation to continual stimulus–patient response assessment. If the level of anesthesia is in doubt, err on the side of an animal that is too lightly anesthetized.

Stimulus assessment is of special importance since the intensity of stimulus applied to an anesthetized animal may rapidly and markedly alter the observed signs (Eger et al., 1972; Steffey, 1983; March and Muir, 2003). A quiet animal with reasonable vital signs may quickly show evidence of light to moderate anesthesia in the presence of intense visceral stimulation despite no change in anesthetic delivery. Common responses to anesthetic dose–stimulus interaction are given in Table 9.14.

More precise quantitative measures of anesthetic depth are of obvious interest for the clinician and essential in research. Measurement of end-expired (alveolar) concentration of inhaled anesthetics allows the clinician to estimate anesthetic depth based on knowledge of the patient and concurrent drug administration but clinical signs are still important. There is continued interest in using electrophysiological approaches to measure depth of anesthesia in both the laboratory and the operating room. For example, it is long known that anesthetic drugs alter the spontaneous electroencephalogram and other electrophysiological measures of CNS function. Notable use of this information is the development of bispectral EEG signal processing for monitoring anesthetic depth (Rampil, 1998). The bispectral index (BIS) is a complex, proprietary EEG parameter that was approved by the US Food and Drug Administration for commercial availability as a monitor of anesthetic effect in human patients. Studies using such technology have shown good correlations with clinical signs in a number of animal species (March and Muir, 2003) but its general application will have to await more detailed information and a decrease in the cost of the equipment. For a more complete review of central nervous system–focused electrophysiological technology applied to anesthetic management of human patients, see Stanski and Shafer 2005.

1. Signs of presurgical anesthesia
   a) Bradycardia, tachycardia, arrhythmia
   b) Arterial hypertension
   c) Pupillary dilation, lacrimation, globe rotation
   d) Tachypnea or breath holding
   e) Deep breathing
   f) Reduced alveolar/arterial $P\text{CO}_2$
   g) Limb/body movement
   h) Salivation, vomition
   i) Swallowing
   j) Laryngeal spasm
   k) Phonation
2. Signs of deep surgical anesthesia
   a) Bradycardia, tachycardia, arrhythmia, cardiac arrest
   b) Arterial hypotension
   c) Pupillary dilation, dry cornea, centrally fixed eye
   d) Shallow breathing, respiratory arrest (*not* breath holding)
   e) Elevated alveolar/arterial $P\text{CO}_2$
   f) Muscle flaccidity

Note: Importance of a given sign in a specific species and/or individual varies.

Neuromuscular Blocking Agents

Diane E. Mason and Christopher L. Norkus

The authors thank HR Adams for the original chapter upon which this is based.

Neuromuscular blocking agents used in clinical medicine act by interfering with the action of the endogenous neurotransmitter acetylcholine (ACh) on the nicotinic cholinergic receptor at the neuromuscular junction (NMJ), thereby inhibiting receptor-coupled transmembrane ion movements necessary to initiate muscle contraction (Bouzat et al., 2004; Unwin, 2005). The end result of this action is skeletal muscle paralysis and muscular relaxation (Bowman, 2006). Neuromuscular blocking (NMB) agents are used in veterinary medicine as adjuncts to general anesthesia. The most common indications for a NMB agent in veterinary medicine are to aid in the placement of an endotracheal tube, to be used concurrently with sedative/hypnotic agents to facilitate mechanical ventilation, to enhance muscle relaxation for a variety of surgical conditions (e.g. ophthalmological procedures), or as part of a balanced anesthetic technique to reduce the amount of inhalation anesthetic required (Keegan, 2015). The sporadic use of NMB agents in veterinary medicine is in stark contrast to the widespread use of NMB agents in human anesthesia and is largely a result of interspecies differences. For example, most species seen in veterinary medicine can be easily intubated with an endotracheal tube after administration of an intravenous anesthetic induction agent without the additional need of a NMB agent, while intubation in man is often more difficult and may necessitate deeper muscle relaxation (Bozeman et al., 2006).

Development

Development of NMB drugs represents a colorful history in the field of pharmacology. Interesting reviews of the course of these events have been presented by Betcher (1977), Bisset (1992), and Lee (2005). Neuromuscular blocking drugs originated with the discovery of curare, a tarlike mixture of plant material used as a poison by South American Indians. The actual ingredients of the poison for arrows, blowgun darts, and spears were known only to a local "pharmacist," who was often the tribal medicine man of a region. Thus the botanical preparations obtained by explorers could not be identified as to content; they were simply classified according to the containers in which they were packaged. Tubo-, para-, or bamboo-curare was contained in cutoff bamboo tubes; this mixture was usually obtained from southern Amazon tribes. The plant origin of tube-curare preparations was primarily Menispermaceae (*Chondrodendron tomentosum*). Calabash-curare was packaged in hollow gourds or calabashes; it was the most active preparation. Pot-curare came in small earthenware pottery from the central part of the Amazon basin; this concoction often contained plants other than Menispermaceae (McIntyre, 1972). The most important constituent isolated from curare was *d*-tubocurarine (Wintersteiner and Dutcher, 1943).

Original studies in the 19th century by Claude Bernard (1856) (Bowman, 2006) demonstrated that curare prevented the muscle contraction elicited by stimulation of the motor nerve. It did not, however, affect the central nervous system (CNS), prevent response to direct stimulation of the muscle, or depress axonal conductance. It was proposed that curare acted at the nerve–muscle junction. Reports since then have substantiated, clarified, and extended observations concerning the neuromuscular blocking properties of curare alkaloids. Early results stimulated active research into the chemical structural requirements of curare-like compounds, leading to the discovery of other types of NMB agents.

Neuromuscular blocking agents possess chemical structural groups that allow interaction of these agents with the nicotinic cholinergic receptor (Brejc et al., 2001). However, these drugs cause distinctly different effects from the endogenous mediator ACh. According

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.
© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.
Companion Website: www.wiley.com/go/riviere/pharmacology

to the drug's mechanism of action at the nicotinic postjunctional receptor, NMB drugs are classified as either competitive nondepolarizing agents or as depolarizing agents. Competitive nondepolarizing NMB agents occupy the receptor so that ACh cannot access its binding site and upon binding these compounds fail to trigger transmembrane ion movement, resulting in muscle paralysis for the duration of their effect. Depolarizing agents act in a more complicated manner and initially cause membrane depolarization, often characterized by muscle fasciculation, before blockade and muscle paralysis occur (Hibbs and Zambon, 2011).

Impulse Transmission at the Somatic Neuromuscular Junction

Prior to discussing individual NMB agents, impulse transmission at the somatic NMJ will be reviewed in relation to sites of action of different drugs. General concepts of cholinergic transmission are discussed in detail in Chapters 6 and 8.

Physiological and Anatomic Considerations

A representation of a somatic NMJ synapse and proposed sites of drug actions are shown in Figure 10.1. Terminal branches of a motor axon lose their myelin sheath and embed within invaginations of the cell membrane of the skeletal muscle cell; these invaginations are termed synaptic gutters. A synaptic gutter, in turn, has many microinvaginations or infoldings, called junctional folds. The space within the synaptic gutter between the nerve ending and the muscle cell is called the synaptic cleft. *Presynaptic* refers to nerve axon elements, whereas *postsynaptic* refers to constituents of the muscle cell.

Vesicular structures localized within cholinergic nerve terminals represent storage sites for ACh (see Chapter 6). As an axonal action potential arrives at the nerve terminal, it increases the release of ACh from the storage vesicles into the synaptic cleft. This step (excitation–secretion coupling) is dependent upon an action potential activating voltage-gated Ca^{++} channels that shift extracellular Ca^{++} into the neuron and/or release Ca^{++} bound to superficial membranes of the nerve terminal. The rise in intracellular Ca^{++} triggers fusion of the storage vesicles with the plasma membrane, and neurotransmitter release. The ACh released into the synaptic cleft binds to specialized receptor sites on the postsynaptic membrane and causes depolarization of the muscle cell. The exclusively nicotinic cholinergic receptors located on the plasma membrane surface of the muscle cell are clustered in high density in the

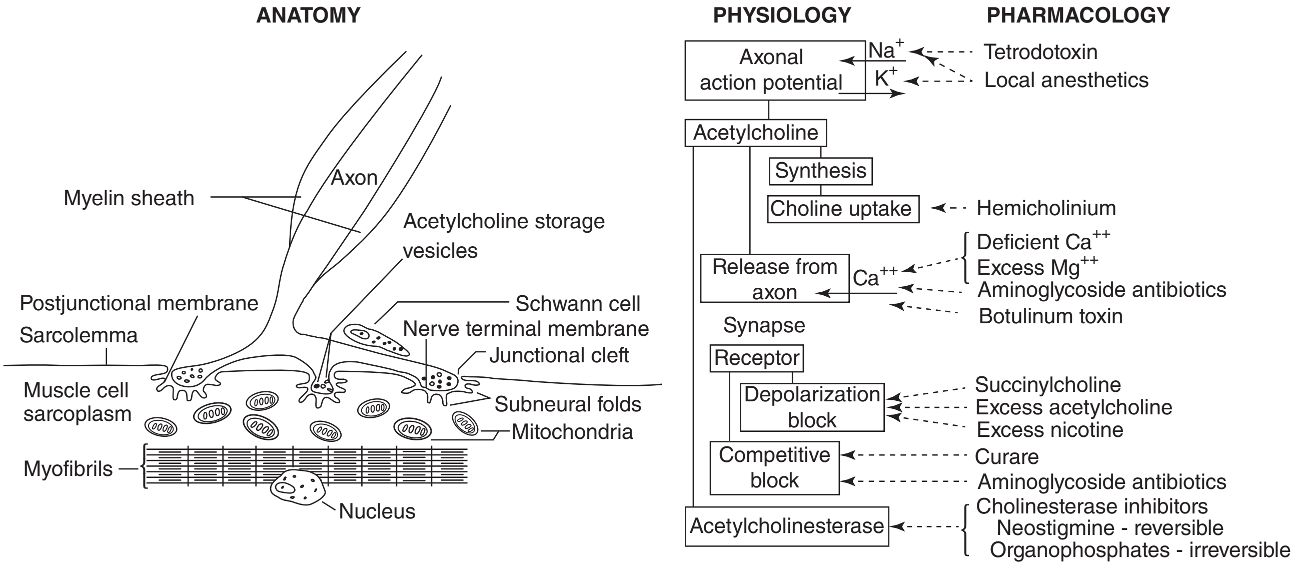

Figure 10.1 Schematic representation of a somatic neuromuscular junction (synapse), related physiological pathways, and proposed sites of action of various pharmacological agents. An axonal action potential (AP) is characterized by an influx of Na^+ and an efflux of K^+. Tetrodotoxin and saxitoxin inactivate Na^+ pathways. Local anesthetics block Na^+ and K^+ pathways. Choline uptake into the neuron is blocked by hemicholinium; synthesis of ACh is prevented. As the AP arrives at the nerve terminal, it instigates inward movement of Ca^{++}; this triggers discharge of ACh into the junctional cleft. A lack of Ca^{++} or an excess of Mg^{++} decreases release of ACh. Aminoglycoside antibiotics also interfere with Ca^{++} -dependent release of ACh. Botulinum toxin inhibits ACh release. Succinylcholine (depolarizing neuromuscular blocking agents) cause persistent depolarization block of the motor end-plate region, as does excess ACh and nicotine. Curare and atracurium (competitive neuromuscular blocking agents) compete with ACh for postsynaptic receptors but do not cause depolarization. Aminoglycoside antibiotics decrease sensitivity of the postsynaptic membrane to ACh. Catabolism of ACh by acetylcholinesterase is inhibited by reversible and irreversible anticholinesterase agents; ACh accumulates. Source: Modified from Hibbs and Zambon, 2011; Couteaux, 1972.

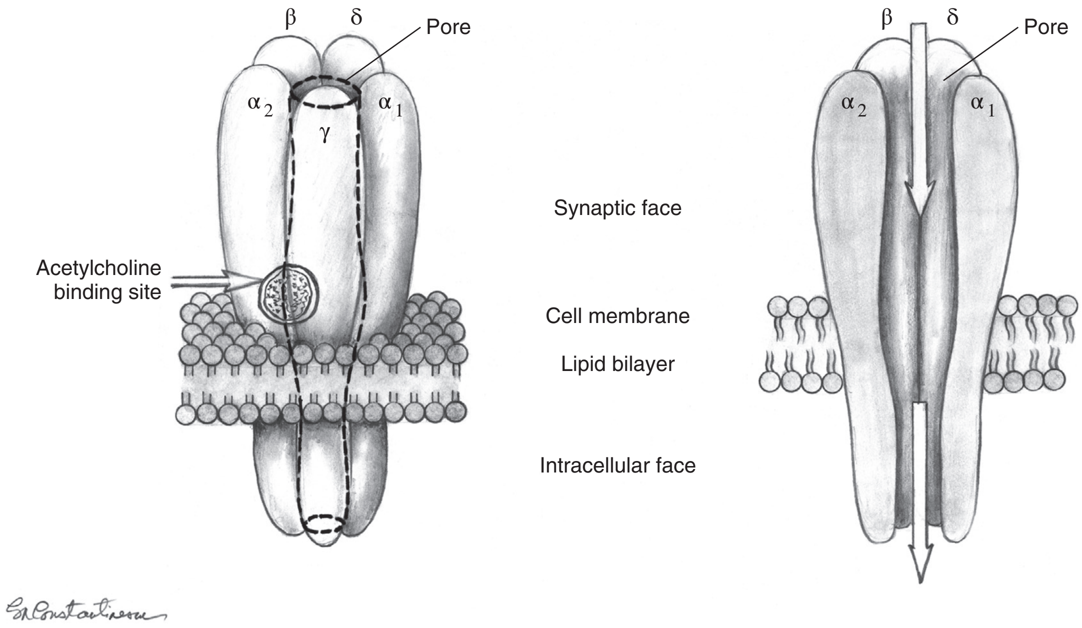

Figure 10.2 Schematic representation of the nicotinic cholinergic receptor. The receptor is embedded across the cell membrane lipid bilayer, presenting a synaptic face to the neuroeffector junction between the neuron and innervated cell, and an intracellular face within the cytoplasm. The receptor comprises a pentameric configuration of four separate subunits with a stoichiometric ratio of $\alpha_2\beta\gamma\delta$; in adult muscle $\alpha_2\beta\varepsilon\delta$. The α subunits contain the primary ligand binding sites for recognition of acetylcholine and related agents. Subunit arrangement forms an internal pore that allows passage of select ions upon receptor activation and resulting membrane depolarization (see text). Source: Redrawn from Unwin et al. (1988) by Dr. Gheorghe M. Constantinescu, University of Missouri.

junctional folds of the postsynaptic membrane (Huh and Fuhrer, 2002).

It requires the activation of a large number of nicotinic cholinergic receptors to excite a single muscle fiber and stimulate muscle contraction. At the same time the process requires a very rapid termination of response. A single synaptic vesicle contains roughly 7000–12,000 molecules of ACh and a single motor axon action potential may trigger the fusion of 40–300 vesicles depending on the species or type of NMJ studied (Steinbach and Wu, 2004). After release into the synaptic cleft the ACh reaches high concentration rapidly, where it can bind to cholinergic receptors. However, ACh released into the synaptic cleft also can bind to the enzyme acetylcholinesterase (AChE), which hydrolyzes ACh to choline and acetate thus inactivating it. All unbound, extraneuronal ACh is rapidly metabolized by the AChE enzyme, which is localized in the motor end-plate region. Although AChE may be bound in part to presynaptic elements, it is concentrated at the postsynaptic membrane (Inestrosa and Perelman, 1990; Hucho et al., 1991). The relative ratio of binding sites for ACh on the nicotinic cholinergic receptor to AChE binding sites at the NMJ is approximately 10 : 1 (Steinbach and Wu, 2004). Due to the rapid rate of hydrolysis of ACh by AChE and the comparatively slow release of ACh from relatively large numbers of nicotinic receptors at the motor end-plate, the concentration of free ACh within the synaptic cleft is rapidly reduced after a single action potential.

The Nicotinic Receptor and Structure–Activity Relationships

The nicotinic cholinergic receptor is a pentameric molecule of about 290 kilodaltons that spans the bilayer of the postsynaptic membrane at the NMJ (Figure 10.2). The receptor comprises five individual subunits in a stoichiometric ratio of α2βγδ; the γ-subunit is replaced by an ε-subunit in muscle from adult animals. Each subunit presents an extracellular and intracellular surface and also contains sequences of hydrophobic amino acids that are the likely regions embedded within the membrane bilayer (Hibbs and Zambon, 2011). The five subunits of each individual receptor complex are elongated perpendicular to the postsynaptic membrane and are arranged circumferentially to form a rosette around a central lumen (Figure 10.2). This central transmembrane channel of the receptor complex represents the membrane pore for ion fluxes instigated by agonist activation of the receptor (Unwin, 2005). Agonist and antagonist binding sites are restricted to the α-subunits (Kistler et al., 1982). Whereas ACh evokes receptor activation upon binding to the α-subunits, occupation of these same sites by antagonists prevents effective receptor activation

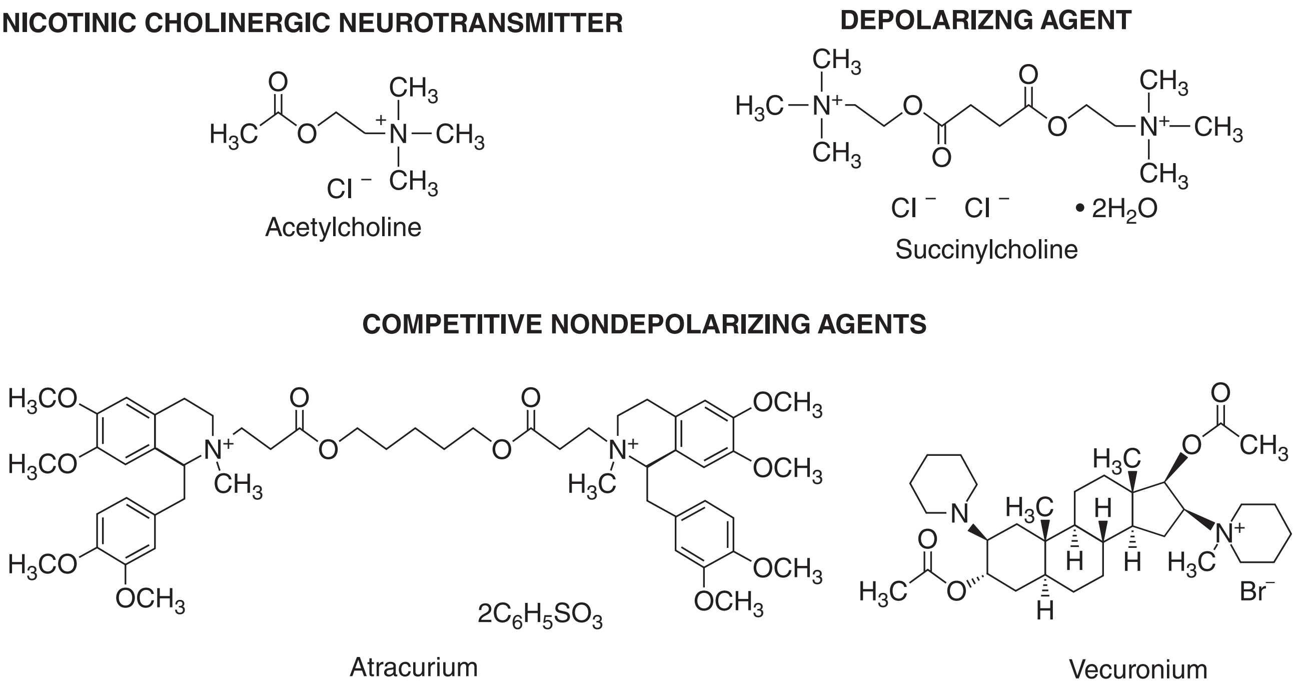

Figure 10.3 Chemical structures of agents interacting with the nicotinic cholinergic receptor at the neuromuscular junction. The cholinergic neurotransmitter, acetylcholine, contains a cationic nitrogen moiety that forms a bond with receptor binding site. Two molecules of acetylcholine must bind to a nicotinic receptor to activate the ion channel. The depolarizing neuromuscular blocking agent, succinylcholine, is depicted. The chemical structure of succinylcholine is equivalent to two acetylcholine molecules fused in sequence. A single molecule of succinylcholine can bind to both of the nicotinic binding sites on the cholinergic receptor inactivating the receptor. Competitive nondepolarizing NMB agents from the benzylisoquinolinium family (atracurium) and the aminosteroid group (vecuronium) are represented. These compounds are complex bulky molecules but contain the important dual cationic nitrogen moieties in a rigid configuration that allows occupation of both of the nicotinic binding sites on the cholinergic receptor and effectively inactivating the receptor.

(Karlin, 2002). The muscle becomes paralyzed, whether in response to a competitive nondepolarizing blocking agent or to transient activation by a depolarizing blocking agent. Chemical structures of several commonly used NMB agents are shown in Figure 10.3 to demonstrate structural differences of the competitive, nondepolarizing and the depolarizing types of NMB agents.

Based on general chemical structural characteristics, Bovet (1951) placed neuromuscular blocking agents into two basic categories. One group is characterized by large, bulky, rigid molecules; members of this group include *d*-tubocurarine, vecuronium, atracurium, and pancuronium, all of which are the competitive, nondepolarizing neuromuscular blockers. The other group is characterized by long, slender, flexible molecules that allow free bond rotation. Decamethonium and succinylcholine are in this group; these agents represent member of the depolarizing NMB agents. The dichotomy in basic structural arrangement of competitive, nondepolarizing and depolarizing agents has been offered as a partial explanation for dissimilar effects evoked by interaction of these agents with the nicotinic cholinergic receptor.

Among other requirements, receptors contain two anionic (negatively charged) binding sites separated by set distances. These sites are essential for electrostatic bonding of the cationic (positively charged) nitrogen moiety of ACh (and exogenous chemicals) to the receptors (Brejc et al., 2001). All NMB agents, are quaternary ammonium compounds, containing the cationic nitrogen regions necessary to interact at the ACh binding site. Despite the variety of chemical structures represented among the modern nondepolarizing NMB agents, a maximum bond distance between the two quaternary groups present in any of these molecules is typically fixed at 1.0 ± 0.1 nm. Depolarizing NMB agents that vary in length and have free bond rotation may have a distance between quaternary ammonium groups up to a maximum bond distance of 1.45 nm (Hibbs and Zambon, 2011).

Occupation of negatively charged binding sites on the receptor by the neurotransmitter, ACh activates influx of Na^+ and flux of K^+ along their respective concentration gradients, resulting in membrane excitation. Occupation of these sites by the molecularly rigid competitive agents stabilizes the receptor so that the membrane channel is not activated. Depolarizing agents initially act similarly to ACh. Because of their flexible structure, they allow initial channel activation and ion flow but for some reason result in a persistent interruption in ion flow through the receptor so that additional changes in electrical potential are not achieved.

Pharmacological Considerations

The NMJ is quite susceptible to alteration by selective pharmacological agents. Various drugs, toxins, electrolytes, and other agents alter in different manners the synthesis, storage, release, receptor interactions, and catabolism of ACh. Several important factors affecting cholinergic transmission are outlined in Figure 10.1.

Hemicholinium is a choline-transport inhibitor that interferes with choline reuptake into cholinergic neurons; although this agent has no current clinical application, it is used widely in research application (Inazu et al., 2013). Acetylcholine synthesis is prevented by lack of choline, classified as an essential nutrient in the B vitamin complex family (Ferguson and Blakely, 2004). Existing vesicular stores of ACh are exhausted upon nerve stimulation, and a gradual weakening and eventual paralysis will result without reuptake and synthesis.

Nerve conduction is affected by only a few substances. Local anesthetics in immediate contact with the motor nerve axon act to stabilize the nerve by inactivating both Na^+ and K^+ channels so that axonal action potential propagation is halted. The puffer fish poison tetrodotoxin and the shellfish poison saxitoxin decrease the permeability of excitable membranes to Na^+ (but not K^+); thus axonal action potentials are not generated and paralysis results. These toxins do not cause an initial depolarization of nerves; they act noncompetitively, are approximately 100,000 times more potent than cocaine or procaine, and are frequently used in research. Clinical cases of fatal food poisoning have also been attributed to ingestion of these substances from their natural source (Cusick and Sayler, 2013).

Botulinum toxin is a potent substance (lethal dose for a mouse is 4×10^7 molecules) produced by *Clostridium botulinum.* It is ingested rarely by humans, more often in cattle, horses, poultry and waterfowl and often is fatal (Johnson et al., 2010). It acts within the motor axon to prevent ACh release into the NMJ by interfering with fusion of cholinergic synaptic vesicles with the plasma membrane (Dressler et al., 2005).

Magnesium ions (Mg^{++}) interfere with release of ACh from the nerve terminal by competing for the transport mechanisms responsible for mobilization of Ca^{++} into the nerve. Magnesium uncouples the excitation–secretion coupling process. An insufficient concentration of Ca^{++} produces similar effects. Magnesium also acts postsynaptically to decrease the effectiveness of ACh to activate receptors.

Aminoglycoside antibiotics (i.e., neomycin–streptomycin group) inhibit release of ACh from motor nerves by decreasing availability of Ca^{++} at superficial membrane binding sites of the axonal terminal, thereby inhibiting the excitation–secretion coupling process. These antibiotics also reduce sensitivity of the postsynaptic membrane to ACh (Adams, 1984).

Cholinesterase inhibitors (see Chapter 8) decrease the hydrolytic activity of AChE and pseudocholinesterase (Taylor, 1991; Hibbs and Zambon, 2011). ACh rapidly accumulates at receptor sites. Muscle fasciculations, spasms, convulsions, and eventually apnea occur after overdosage with cholinesterase inhibitors.

Postjunctional Mechanisms of Neuromuscular Blockade

The pharmacological effects of clinically useful NMB drugs are a result of their direct alteration of the ability of ACh to activate postsynaptic nicotinic cholinergic receptors (Hibbs and Zambon, 2011).

Competitive Nondepolarizing Agents

Nondepolarizing NMB agents compete with ACh for available nicotinic cholinergic receptors at the neuromuscular postsynaptic membrane and, once occupying these receptors, prevent the ability of Ach to produce a motor response. The historical prototype of this group of drugs is *d*-tubocurarine (tubocurarine chloride, USP, Tubarine), a naturally occurring monoquaternary alkaloid obtained from the bark of the South American plant *Chondrodendron tomentosum*. Today *d*-tubocurarine is not used clinically and has long been replaced with similarly acting agents, including atracurium, cisatracurium, pancuronium, vecuronium, rocuronium, mivacurium, doxacurium, and, most recently, gantacurium. Pharmacological characteristics of representative NMB agents in modern use are summarized in Table 10.1.

Ultra refined experimental techniques helped verify the primary site of action of competitive blocking agents (Bowen, 1972; Hubbard and Quastel, 1973). Although *d*-tubocurarine binds to cholinergic receptors in the same region as ACh, and appears to have the same or similar affinity as ACh for cholinergic receptors, *d*-tubocurarine does not exhibit receptor-activating properties, it has no depolarizing activity, and therefore does not cause a motor end-plate potential. Moreover, the *d*-tubocurarine–receptor interaction renders affected receptors unavailable for interaction with ACh. ACh-induced end-plate potentials are reduced to subthreshold levels or abolished in curarized muscles. In the absence of induced end-plate potentials and subsequent muscle action potentials, the muscle relaxes and is, in fact, paralyzed.

Based on competitive interaction between nondepolarizing agents and ACh, cholinesterase inhibitors were

Table 10.1 Characteristics of neuromuscular blocking agents

Drug	Onset	Duration	Elimination	Dosing	Constant rate infusion
Depolarizing agents					
Succinylcholine	1–2 min	6–10 min	Hydrolysis by plasma cholinesterase	0.3–0.4 mg/kg (C) 0.1–0.2 mg/kg (F) 0.12–0.15 mg/kg (E)	
Competitive nondepolarizing agents					
Atracurium	5 min (C)	30–40 min (C)	Ester hydrolysis, Hofmann elimination	0.1–0.2 mg/kg (C) 0.1–0.25 mg/kg (F) 0.07–0.15 mg/kg (E)	0.18–0.36 mg/kg/h (C) 0.17 mg/kg/h (E)
Cisatracurium	5 min (C)	30–40 min (C)	Hofmann elimination	0.075–0.3 mg/kg (C) 0.05–0.3 mg/kg (F)	
Doxacurium	40 min (C)	100–120 min (C)	Renal and biliary elimination of unchanged drug	3.5 μg/kg (C)	
Vecuronium	5 min (C)	30–40 min (C)	Hepatic metabolism biliary and renal excretion	0.1 mg/kg (C) 0.025–0.1 mg/kg (F) 0.1 mg/kg (E)	
Rocuronium	1–2 min (C)	20–30 min (C)	Hepatic uptake and Biliary excretion	0.1–0.6 mg/kg (C) 0.1–0.6 mg/kg (F) 0.3–0.6 mg/kg (E)	0.2 mg/kg/h (C)
Pancuronium	5 min (C)	30–60 min (C)	Hepatic metabolism and renal elimination of active metabolites	0.07–0.1 mg/kg (C) 0.06–0.1 mg/kg (F) 0.12 mg/kg (E)	
Gantacurium	1–2 min (C)	5 min (C)	Ester hydrolysis, cysteine adduction	0.06 mg/kg (C) 0.06 mg/kg (F)	

Species indicated are canine (C), feline (F) and equine (E).

found to be effective in antagonizing the effects of these blocking agents (Taylor, 2011). Cholinesterase inhibitors prevent the enzymatic catabolism of ACh. More ACh is available for interaction with cholinergic receptors and thereby decreases effectiveness of competitive blocking agents. This relationship has been exploited clinically in successful efforts to terminate the effects of nondepolarizing agents. However, cholinesterase inhibitors do not antagonize effects of the other class of neuromuscular blockers, the depolarizing drugs.

Nondepolarizing NMB agents are classified as pachycurares, or bulky molecules having their amine functions incorporated into rigid ring structures. Two groups of synthetic pachycurares contain the drugs in common use in medicine today: the aminosteroids and the benzylisoquinoliniums. The aminosteroids maintain their interonium distance by an androstane skeleton while the benzylisoquinoliniums maintain this atomic distance by linear diester-containing chains (Lee, 2001).

Benzylisoquinolinium Compounds

Atracurium is a *bis*-benzyltetrahydroisoquinolinium with isoquinolinium nitrogens connected by a diester-containing hydrocarbon chain. Its action is intermediate with a dose-dependent onset of action of approximately 5 minutes and duration of approximately 30 minutes in dogs (Jones, 1983). Repeated doses are generally not cumulative, so longer-term maintenance can be achieved via a constant-rate infusion (Playfor et al., 2000). Atracurium undergoes ester hydrolysis, Hofmann elimination reaction, and likely other nonhepatic routes for biotransformation, making the drug appropriate for use in hepatic or patients with renal insufficiency. In a Hofmann elimination reaction, a quaternary ammonium group is converted to a tertiary amine by cleavage of a carbon–nitrogen bond. This process does not require enzymatic activity. Hofmann elimination is both a pH and temperature-sensitive reaction in which higher pH and temperatures favor drug breakdown. Clinical consequences of this are important in that patient acidemia and hypothermia may hinder drug breakdown (Playfor et al., 2000). Additionally, the drug should be kept refrigerated and is supplied at a pH of 3.25–3.65 to slow degradation.

The marketed atracurium product has ten isomers. These isomers are separated into three geometric isomer groups that have been designated cis–cis, cis–trans, and trans–trans according to their configuration about the tetrahydroisoquinoline ring system (Wastila et al., 1996). Cisatracurium is the 1R cis-1'R cis isomer of atracurium and represents approximately 15% of the marketed atracurium product's weight yet produces roughly 50% of atracurium's neuromuscular blocking activity. Cisatracurium (Nimbex) is available as a standalone product separate from atracurium. Cisatracurium is metabolized by Hofmann elimination entirely. The presence of portosystemic shunt and hepatic insufficiency did not affect the rate of onset or duration of action of cisatracurium in dogs receiving 0.1 mg/kg IV followed by repeat doses of 0.03 mg/kg IV (Adams et al., 2006). In general, cisatracurium has a similar duration and clinical effects to atracurium.

Following intravenous injection, atracurium spontaneously decomposes into laudanosine and a quaternary monoacrylate. Laudanosine in high quantities is a CNS stimulant and may result in seizures, hypotension, and tachycardia (Chapple et al., 1987). Laudanosine, unlike atracurium, is dependent upon hepatic clearance, so theoretically laudanosine plasma concentrations may become elevated in patients with hepatic dysfunction. Practically, laudanosine-induced toxicity is unlikely in clinical patients unless atracurium is used in large doses and/or for prolonged periods (Chapple et al., 1987). Nonetheless, another aminosteroid may be selected to avoid this remote issue entirely.

d-Tubocurarine, the prototypical benzoisoquinolone NMB agent, is associated with histamine release and resulting hypotension. Although atracurium has the potential to result in histamine release, this requires several times the ED_{95} dose (effective dose producing a 95% reduction in twitch height) before appreciable amounts of histamine are released, making problems such as hypotension and tachycardia rarely observed in clinical cases (Scott et al., 1986; Hackett et al., 1989). In isoflurane-anesthetized dogs, 0.2 mg/kg IV atracurium did not result in significant changes to intraocular pressure, mean arterial pressure, heart rate, or central venous pressure (McMurphy et al., 2004). A notable exception to atracurium and cisatracurium's minimal cardiovascular profile may be in dogs with X-linked muscular dystrophy. Affected golden retrievers in one retrospective study that received 0.1 mg/kg cisatracurium had marked increases in heart rate (115 ± 64%) and blood pressure (33.5 ± 31%) that lasted 10 and 30 minutes, respectively (Staffieri et al., 2011).

Atracurium has been widely used with positive clinical success across a variety of species including, but not limited to, dogs, cats, and horses. In horses and dogs, the use of atracurium in conjunction with aminoglycoside antibiotics, specifically gentamycin, has been shown to augment neuromuscular blockade; however, this effect appears minimal and has not been reported to impact recovery quality (Hildebrand and Hill, 1994; Martinez et al., 1996). Atracurium has also been investigated for use in a urethral flushing solution in cats and dogs to help facilitate manual bladder expression in patients with spinal cord injuries and in obstructive urethral plugs (Galluzzi et al., 2012; Galluzzi et al., 2015).

Two additional benzylisoquinolinium compounds, mivacurium and doxacurium, are reported in the veterinary literature but are infrequently used in clinical practice today. Mivacurium (Mivacron) is a short-acting NMB agent in humans (15–20 minutes' duration); however, this duration of effect appears markedly prolonged in dogs. Although mivacurium resulted in minimal hemodynamic changes, in dogs administered 0.05 mg/kg IV it appeared to have a long half-life and slow clearance under halothane anesthesia with duration of effect up to 151.0 ± 38.50 minutes (Smith et al., 1999a, 1999b). Clinical observations in cats suggest that mivacurium has a shorter duration of action compared to that in dogs. Mivacurium is unique amongst the benzylisoquinolinium compounds in that it is metabolized by plasma cholinesterases to a monoester and this attribute, as a result of interspecies differences in plasma cholinesterases, may explain its variable duration of action between species. At the time of writing, mivacurium is not currently available within the United States.

Doxacurium (Nuromax) has a slow onset of action and long duration (>50 minute) of effect in man. Doxacurium may result in an increased propensity for histamine release and cardiovascular side effects when compared to other benzylisoquinolinium compounds. Work in dogs would suggest that 2.1 μg/kg IV approximates an ED_{50} while 3.5 μg/kg IV approximates an ED_{95} with duration of action at 108 ± 31 minutes (Martinez et al., 1996). Due to increased cost, minimal reported advantage, and lack of availability and clinical experience, atracurium is typically selected over other available benzylisoquinolinium compound for veterinary patients.

Aminosteroid Neuromuscular Blocking Agents

Pancuronium (Pavulon) was the first aminosteroid to be introduced as a NMB agent. The drug has a dose-dependent onset of approximately 5 minutes and long duration of action, up to 60 minutes in the dog (Gleed and Jones, 1982). Because repeated doses have a cumulative effect, constant-rate infusions are avoided. A large proportion of pancuronium is excreted by the kidney. The remainder is metabolized via the liver, making the duration of action increased in patients with renal and hepatic dysfunction. In addition to exerting its effect on postsynaptic nicotinic receptors at the NMJ, pancuronium also has a vagolytic effect by blocking cardiac muscarinic action, which may result in an increase in heart rate. Decreases to systemic vascular resistance, pulmonary vascular resistance, and coronary and renal artery dilation via prostaglandin I_2 release have also been noted in the dog (Hackett et al., 1989; Sai, 1998). In dogs, cats, pigs, and horses doses between 0.06 and 0.12 mg/kg IV have been reported (Gleed and Jones, 1982; Hildebrand et al., 1989; Miller et al., 1978; Veres-Nyéki et al., 2012). Pancuronium is stable at room temperature for 6 months.

Removal of a single positively charged methyl group from pancuronium creates vecuronium, an aminosteroid NMB agent that is essentially devoid of cardiovascular effects (Morris et al., 1983; Jones, 1985b). This molecular modification has several other important clinical implications, including molecular instability in solution which necessitates vecuronium be kept as a lyophilized powder and only reconstituted immediately prior to administration with stability of only 24 hours once reconstituted. Additionally, vecuronium has a shorter duration of action than pancuronium and an increase in lipid solubility, which results in greater biliary elimination than with pancuronium (Hill et al., 1994). Vecuronium has a dose-dependent onset of action of approximately 5 minutes and generally an intermediate duration of action of approximately 30 minutes, making its clinical utility similar to atracurium.

Vecuronium undergoes both hepatic metabolism, biliary clearance from the liver as parent compound, and about 25% undergoes renal elimination. Patients with renal or hepatic insufficiency may experience prolonged recovery if increased doses of vecuronium are administered. Dogs with diabetes mellitus have been shown to have a shorter duration of effect from vecuronium based upon both tactile train-of-four (TOF) and electromyography (Clark et al., 2012). The potency and duration of vecuronium does not, however, appear to be altered in dogs with autosomal recessive centronuclear myopathy (Martin-Flores et al., 2015b). In horses, it appears that a dose greater than 0.1 mg/kg IV would be needed for complete neuromuscular blockade and that this effect would have a uniquely long duration in this species, lasting over 120 minutes (Martin-Flores et al., 2012a, 2012b). Additionally, one case report documents that a dosage of 0.5 mg/kg IV edrophonium failed to completely reverse prolonged vecuronium-induced neuromuscular blockade in anesthetized dog as judged by peripheral nerve stimulation (Martin-Flores et al., 2011).

Rocuronium bromide (Zemuron), another member of the aminosteroid NMB agent family, lacks the acetyl ester that is found in the steroid nucleus of pancuronium and vecuronium and is less potent but similar in molecular weight to vecuronium. Rocuronium has a more rapid onset compared with atracurium and vecuronium, but similar duration of action (Carson et al., 1990; Gyermek et al., 2002). Additionally, rocuronium appears to be largely devoid of cardiovascular side effects, including no significant histamine release (Hudson et al., 1998). The drug is eliminated primarily via hepatic clearance while a small fraction is eliminated via the kidney. Detectable levels of rocuronium metabolites are not found. Rocuronium is stable for 60 days at room temperature. Rocuronium at clinically relevant concentrations may also bias the accuracy of lithium dilution cardiac output monitoring by interacting with the LiDCO sensor (Ambrisko et al., 2013).

In cats, a dosage of 0.6 mg/kg IV rocuronium had an onset time of 46 ± 11 seconds, produced no change to subject heart rate, and took 20.7 ± 5.4 minutes for TOF ratios to return to 0.9, a level consistent with full recovery from neuromuscular blockade (Auer and Mosing, 2006; McGrath and Hunter, 2006). Sixty seconds after rocuronium administration in cats, paralysis of the internal laryngeal muscles and conditions suitable for endotracheal intubation occurred that were comparable to topical lidocaine (Moreno-Sala et al., 2013). In dogs, rocuronium at 0.3 mg/kg and 0.6 mg/kg IV resulted in an onset of neuromuscular blockade in 2 ± 0.9 minutes and 1.1 ± 0.6 minutes with total recovery occurring at 23.8 ± 6.6 minutes and 31.9 ± 6.5 minutes respectively (Auer, 2007). Following a loading dose of 0.5 mg/kg IV, rocuronium was found to be suitable for constant-rate infusion at 0.2 mg/kg/h for up to 146 minutes (Alderson et al., 2007). Doses of rocuronium as low as 0.03–0.075 mg/kg IV in isoflurane-anesthetized dogs resulted in a centralized globe position and acceptable conditions for ophthalmic procedures (Briganti et al., 2015). In horses undergoing ophthalmic surgery, a dose of 0.3 mg/kg IV rocuronium produced effective neuromuscular blockade in 2.3 ± 2 minutes with a central globe position in 31 ± 2.8 seconds and a clinical duration of 32 ± 18.6 minutes in all 20 horses studied (Auer and Moens, 2011).

Asymmetric Mixed-onium Chlorofumarates

Gantacurium represents a new class of nondepolarizing NMB agents called asymmetric mixed-onium chlorofumarates, which are structurally distinct from the traditional aminosteroids and benzylisoquinolinium compounds. Gantacurium has an ultrashort duration of action and is degraded in plasma by pH sensitive chemical hydrolysis and inactivation by cysteine adduction. It does not undergo Hofmann elimination. In dogs anesthetized with thiopental, nitrous oxide, and isoflurane, the ED_{95} was 0.06 mg/kg IV with an onset time of 107 seconds and duration of action of 5.2 minutes (Heerdt et al., 2004). In cats following dexmedetomidine and propofol, IV gantacurium at 0.5 mg/kg abolished laryngospasm in 100% of cats and induced apnea for 3 ± 1.5 minutes (Martin-Flores et al., 2015a). At clinical doses, cats and dogs do not appear to have appreciable cardiovascular effects; however, in humans, transient cardiovascular side effects were observed at doses beginning at three times the ED_{95} and were consistent with histamine release (Belmont et al., 2004). Recovery is accelerated with AChE inhibitors such as edrophonium. In humans, exogenous administration of cysteine can also accelerate the antagonism of gantacurium-induced neuromuscular blockade. Gantacurium is not stable in aqueous solution and, like vecuronium, is provided as a lyophilized powder that is reconstituted prior to administration.

Trisquaternary Ether Neuromuscular Blocking Agents

Two drugs are represented in this class of compounds that currently have no clinic significance for use in North America, primarily due either to significant side effects or lack of a currently available marketed product. Gallamine

(Flaxedil) is a NMB agent first developed in 1947 (Rhagavendra, 2002). Its desirable qualities were rapid onset of action (3 minutes) and intermediate to long duration of action in the range of 40 minutes. Gallamine has significant parasympatholytic activity and is associated with tachycardia and hypertension (Lee, 2001; Clark and Mitchelson, 1976). Gallamine can also cause histamine release. Approximately 1 mg/kg gallamine causes complete muscle paralysis in both dogs and cats within 1–2 minutes after IV injection and lasts 15–20 minutes. A hypotensive response may be induced in cats with gallamine but is infrequently observed in dogs.

Alcuronium (Alloferin) is another trisquaternary ether NMB agent whose profile is distinguished by a long duration of effect, rendering it generally less desirable than the short to intermediate acting agents (Diefenbach et al., 1995). The mean duration of effect for alcuronium reported in dogs is 70 minutes (Jones et al., 1978). This agent relies entirely on renal elimination for its clearance, undergoing no biodegradation, and relevant concentrations of alcuronium can still be detected in the plasma up to 12 hours postinitial administration of neuromuscular blockade (Diefenbach et al., 1995). This agent is not marketed for use within the United States.

Depolarizing Agents

Succinylcholine chloride, USP (Quelicin, Anectine, Sucostrin, Suxamethonium), and decamethonium bromide, USP (Syncurine, C-10), are members of the depolarizing group of NMB agents. These drugs exert their paralytic effects by interfering with ACh-mediated depolarization of the postsynaptic membrane. In contrast to the well-defined mechanism of the competitive agents, certain aspects of the mechanism(s) of depolarizing neuromuscular blockers are continually debated.

Only succinylcholine is currently available for use within veterinary medicine as a depolarizing NMB agent. However, its utility has dwindled and even this agent has largely been replaced by newer nondepolarizing NMB agents because of succinylcholine's side-effect profile and potential patient monitoring challenges. Succinylcholine is composed of two molecules of ACh linked back to back through acetate methyl groups. Succinylcholine, like ACh, stimulates cholinergic receptors at the NMJ and at nicotinic ganglionic and muscarinic autonomic sites, ultimately opening the ion channel at the nicotinic cholinergic receptor. Succinylcholine elicits a prolonged depolarization of the neuromuscular end-plate that does not allow the postsynaptic membrane to completely repolarize and therefore renders the neuromuscular motor end-plate unresponsive to the normal action of ACh. Because of the initial stimulatory depolarizing action, transient contraction of muscle cells occurs after administration of succinylcholine. Clinically, this is characterized in the intact animal by asynchronous muscular contractions of the head, body trunk, and limbs. Fasciculations are not always apparent in anesthetized animals. Because of the persistent depolarization of the postsynaptic nicotinic membrane, continued impulse transmissions are blocked and a flaccid paralysis ultimately ensues. The mechanism of depolarizing NMB agent action has historically been described as biphasic.

Phase I block: Initially a phase I block results from depolarization of the neuromuscular motor end-plate region by succinylcholine resulting in an increased and persistent permeability of the postsynaptic membrane to sodium and potassium ions, specifically an influx of sodium ions into the cell and an efflux of potassium ions out of the cell. The ion channel pores subsequently close and become inactivated. As a result, ACh cannot act as a neurotransmitter, and impulse transmission to evoke a muscle response fails. The membrane potential must be reset in order for the channel to be reactivated again. When Ach causes depolarization it is immediately hydrolyzed by AChE within the synaptic cleft and its effect is very short lived. Succinylcholine causes a persistent alteration in membrane potential because it is not hydrolyzed but must slowly diffuse away from the NMJ and be metabolized by plasma cholinesterases. It should be pointed out that ACh, when in excess, also causes persistent depolarization block of cholinergic synaptic junctions (Appiah-Ankam and Hunter, 2004).

Phase II block: Phase II block occurs in some instances after prolonged exposure or large doses of a depolarizing agent and motor end-plate sensitization and is characterized by a change from the depolarizing block to one that more closely resembles the effect of nondepolarizing NMB agents. The actual mechanisms involved are poorly understood and opinion is contradictory as to this transition. Zaimis (1959) believes, for example, that confusion has occurred because in some species some blocking agents have a "dual mechanism"; that is they cause some effects that resemble depolarization block and cause other effects that resemble competitive blockade (Galindo and Kenney, 1974).

After exposure of isolated nerve-muscle preparations to succinylcholine, the initial peak level of depolarization subsides. Subsequently, the end-plate becomes transiently sensitive to depolarizing agents. Gradually, a competitive-like blockade results and seems to be at least partially susceptible to reversal by cholinesterase inhibitors. Though the overall importance of phase II block has not been clearly defined for depolarizing NMB agents, its potential for occurrence and recognition is important.

As a group, the depolarizing NMB agents cause depolarization of receptor areas of muscle fibers sometime during their course of action. In general, unlike nondepolarizing NMB agents, administration of an AChE inhibitor (e.g., edrophonium, neostigmine) will not reverse the effects of depolarizing NMB agents such as succinylcholine and may in fact delay recovery.

Succinylcholine has a rapid onset of effect and an ultrashort duration of action, which has made the agent historically ideal to assist in rapid human endotracheal intubation. The short duration of action (approximately 6–10 minutes) of succinylcholine is due to its rapid hydrolysis by plasma cholinesterase (psuedocholinesterase, butyrlcholinesterase) to succinylmonocholine and choline. Because there is limited plasma cholinesterase activity at the NMJ, the neuromuscular blockade that occurs from succinylcholine is terminated by the drug's diffusion away from the NMJ back into the circulation. This has important clinical consequences in that the drug is not reversible by AChE inhibitors and factors that decrease plasma cholinesterase activity may prolong recovery. Common factors seen in veterinary patients that may decrease plasma cholinesterase activity include hepatic disease, advanced age, malnutrition, neoplasia, pregnancy, burns, monoamine oxidase inhibitors, terbutaline, esmolol, and metoclopramide (Birch et al., 1956; Lepage et al., 1985; Kao et al., 1990; Barabas et al., 1986).

Hansson (1956) reported that the IV ED_{50} (dose that reduced muscle twitch by 50%) of succinylcholine in the sciatic nerve-gastrocnemius muscle preparation of anesthetized dogs was 0.045–0.060 mg/kg. This dose did not effectively paralyze the respiratory muscles, however, and 0.085 mg/kg was required to induce transient apnea, whereas 0.11 mg/kg and 0.22 mg/kg were needed to cause apnea for 18–21 minutes and 23–27 minutes, respectively. In unanesthetized dogs, IM administration of 0.12 mg/kg succinylcholine caused ataxia in 5 minutes and forced abdominal respiration in 7 minutes; recovery was apparently complete in 30 minutes. In clinical situations, 0.3 mg/kg succinylcholine administered intravenously will usually afford good muscle relaxation in dogs, whereas in the cat, 1 mg/kg may be required. In dogs, Hansson (1956) reported that 0.15 mg/kg succinylcholine was effective in paralyzing the diaphragm during thoracotomy procedures. However, Eyster and Evans (1974) suggested the use of 0.5 mg/kg succinylcholine for muscle relaxation in dogs during thoracotomy for open-heart surgery. This dose was also reported to control muscle twitches evoked by inadvertent stimulation of nerves during use of electrocautery. Duration of paralysis varies and should be closely monitored.

In rhesus monkeys, 1–2 mg/kg succinylcholine administered intravenously has been used for restraint for tuberculosis testing and endotracheal intubation (Lindquist and Lau, 1973). In pigs, approximately 2 mg/kg succinylcholine is effective. Much smaller amounts (0.01–0.02 mg/kg) are required in cattle and sheep. Hansson (1956) reported that 0.13–0.18 mg/kg succinylcholine is required to immobilize unanesthetized horses. However, the generally accepted dose of succinylcholine in horses, when used alone, is 0.088 mg/kg (Lumb and Jones, 1973).

Succinylcholine historically has been used without anesthesia in horses for casting and restraint during brief surgical procedures such as castration. This practice is not condoned, because no anesthesia is afforded for painful procedures, severe fright is evoked, and pronounced cardiovascular disturbances and even myocardial damage may result. Succinylcholine should not be used as a sole restraining agent during surgical procedures but only in conjunction with a general or local anesthetic.

Frequent side effects from succinylcholine have resulted in the drug largely being replaced in veterinary medicine by newer agents. Succinylcholine stimulates all cholinergic autonomic receptors, including nicotinic receptors on both sympathetic and parasympathetic ganglia and muscarinic receptors in the sinus node of the heart (Galindo and Davis, 1962). As a prominent clinical manifestation of generalized autonomic stimulation, cardiac dysrhythmias, including sinus bradycardia, junctional ectopy, and ventricular dysrhythmia, may occur. At lower doses negative chronotropic effects predominate and at higher doses tachycardia may occur.

In humans, the administration of succinylcholine to an otherwise healthy patient raises plasma potassium levels by approximately 0.5 mEq/l. This phenomenon results because with channel activation by acetylcholine, sodium moves into the cells, and potassium exits to the extracellular space. This mild increase in potassium is generally well tolerated in healthy patients and does not result in arrhythmias. However, in patients with preexisting hyperkalemia the additional rise in plasma potassium levels could be of clinical concern. The combination of severe metabolic acidemia and hypovolemia has, in both rabbits and man resulted, in severe and life threatening hyperkalemia (Antognini and Gronert, 1993; Schwartz et al., 1992).

Succinylcholine may cause a rise in intraocular pressure (IOP). The mechanism by which the drug increases IOP is not known but may involve contraction of tonic myofibrils or choroidal blood vessel dilation or both. In man the increased IOP occurs within 1 minute after injection, peaks between 2 and 4 minutes, and subsides by 6 minutes (Pandey et al., 1972). Succinylcholine is also known to increase intragastric pressure, presumed to be due to fasciculation of abdominal skeletal muscles. Succinylcholine can be a potential trigger for malignant hyperthermia in susceptible patients and

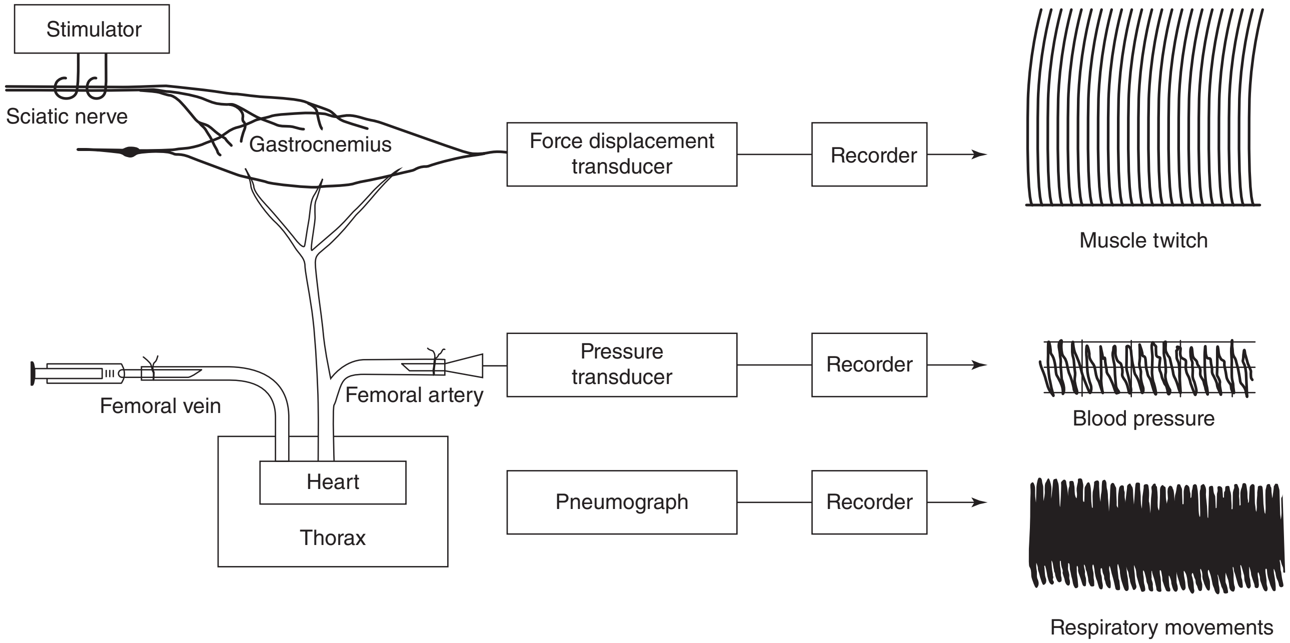

Figure 10.4 Schematic representation of a sciatic nerve-gastrocnemius muscle preparation in an anesthetized cat. Stimulation of the isolated and decentralized sciatic nerve evokes contraction (muscle twitch) of the gastrocnemius muscle. Femoral arterial blood pressure and respiratory movements can be measured concurrently. Neuromuscular blocking drugs can be administered intravenously and changes in muscle twitch height observed.

produce malignant hyperthermia-like episodes, and has the potential to increase intracranial pressure (Minton et al., 1986). Muscle pain, increases to serum creatine kinase, and myoglobinemia have all been reported in man following the drug's administration (Brodsky et al., 1979; McLoughlin et al., 1992).

Pharmacological Effects of Neuromuscular Blocking Agents

When administered, NMB agents are given only to anesthetized patients to provide relaxation of skeletal muscles. It should be remembered that NMB agents do not possess analgesic or amnestic properties and other drugs must be utilized for these effects. Because of a narrow therapeutic index, the clinical usage of NMB agents necessitates strict oxygen supplementation and assisted ventilation in conjunction with qualified supervision by experienced personnel. Said personnel must be thoroughly familiar with the indications, limitations, and adverse effects of NMB agents, principles of monitoring, as well as familiarity with the use of their reversal agents.

Skeletal Muscle

Competitive Neuromuscular Blocking Agents

Nondepolarizing curare-like drugs interact with nicotinic cholinergic receptors of skeletal muscle cells and render them insensitive to the transmitter function of Ach in a dose-dependent fashion. Flaccid paralysis may ultimately occur. Neither axonal conductance nor response to direct stimulation of muscle is blocked by nondepolarizing NMB agents.

A schematic representation of an in vivo nerve-muscle preparation is shown in Figure 10.4. This sciatic nerve-gastrocnemius muscle preparation has been used to examine the actions and pharmacological interactions of NMB agents. In this preparation, electrical stimulation of the sciatic nerve causes contraction (kg of isometric tension) of the gastrocnemius muscle.

Figure 10.5 demonstrates the neuromuscular blocking effect of *d*-tubocurarine on the stimulated muscle twitch of the sciatic nerve-gastrocnemius muscle preparation of a cat, as described in Figure 10.4. Provided a consistent supramaximal stimulus is delivered at a frequency of no greater than once every 7–10 seconds, a depression in muscle twitch response is not seen until approximately 75% of nicotinic cholinergic receptors are blocked. Loss of muscle twitch in response to electrical stimulation requires 90–95% blockade of cholinergic receptors on the motor end-plate (Kelly and Brull, 1993). In this example, muscle twitch quickly decreases after IV injection of *d*-tubocurarine, reaches peak depression within a few minutes, and then gradually returns to normal in approximately 15 minutes. Tubocurarine does not evoke an initial increase in muscle twitch; this lack of facilitation is a consistent finding with nondepolarizing agents.

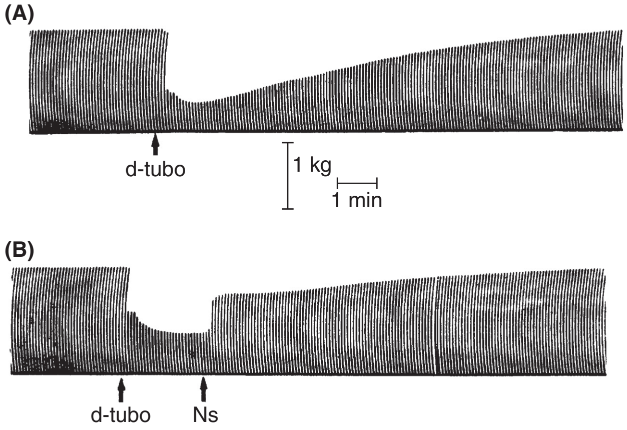

Figure 10.5 Neuromuscular blocking effect of *d*-tubocurarine (*d*-tubo) and reversal of the *d*-tubo by neostigmine (Ns) in a sciatic nerve-gastrocnemius muscle preparation of a cat. The cat was anesthetized with pentobarbital; muscle twitch was monitored as described in Figure 10.4. (**A**) Typical depression of muscle twitch by *d*-tubo (0.2 mg/kg) administered intravenously at designated arrow. (**B**) Antagonism of *d*-tubo (0.2 mg/kg) induced depression of muscle twitch by Ns (0.1 mg/kg). Agents were administered intravenously at arrow. Notice rapid antagonism of the neuromuscular blocking effect of *d*-tubo by Ns. Compare this with the lack of antagonism by Ns of the muscle twitch depressant effect of succinylcholine in Figure 10.6.

Antagonism of the neuromuscular blocking effects of *d*-tubocurarine by administration of a cholinesterase inhibitor, neostigmine, is shown in Figure 10.5. By comparing the two tracings in this figure, it is readily apparent that neostigmine markedly hastens recovery from muscle twitch depression caused by *d*-tubocurarine. This antagonistic interaction is primarily attributed to the anticholinesterase activity of neostigmine. Inhibition of cholinesterase delays the catabolic breakdown of ACh and allows its accumulation at receptor sites. Newly available ACh, now in increased concentration at the postsynaptic membrane, effectively competes with *d*-tubocurarine for the cholinergic receptors. ACh-mediated depolarization of the end-plate, muscle action potentials, and muscle contraction are restored; muscle twitch quickly returns to normal.

The sensitivity to the range of receptor blockade represented in the single twitch muscle preparation of Figure 10.4 is narrow and therefore limits its clinical usefulness as a measure of receptor blockade. In clinical situations, a TOF stimulation pattern is often used to determine the extent of blockade present when NMB agents are being used. Four supramaximal stimuli are delivered at a frequency of 2 Hz and, in normal muscle, four clearly separated twitch responses can be observed in the muscle, which ideally are quantified in amplitude via the use of mechanomyography or acceleromyography (Kelly and Brull, 1993). After administration of a nondepolarizing NMB agent, the TOF stimulation pattern will elicit muscle responses that exhibit fade. The degree of fade is proportional to the extent of receptor blockade. The amplitude of the fourth twitch response (T4) compared to the amplitude of the first twitch response (T1) gives a T4/T1 ratio or TOF ratio. With no blockade the TOF ratio is 1.0. The T4 amplitude will start to decrease when 70–75% of receptors are blocked by a nondepolarizing NMB agent. If the T4 response is lost completely, approximately 80% of the motor end-plate cholinergic receptors are blocked. If T3 and T2 responses disappear, this represents 85% and then 85–90% of receptor occupancy. When 90–95% of receptors are occupied at the NMJ then T1 through T4 will have disappeared (Kelly and Brull, 1993). In order to assess recovery from neuromuscular blockade, a TOF ratio of 0.9 should be achieved before an animal is deemed suitably recovered to be extubated (Ali et al., 1970). Reversal of a nondepolarizing NMB agent can be safely administered when a TOF count is at least demonstrating two twitches or greater (Viby-Mogenson, 2000; Jones et al., 2015).

Depolarizing Neuromuscular Blocking Agents

Succinylcholine elicits transient muscle fasciculations prior to causing neuromuscular paralysis, due to initial depolarization of the motor end-plate and is characterized in the intact animal by asynchronous muscular contractions of the head, body trunk, and limbs.

The in vivo neuromuscular blocking effect of a small dose of succinylcholine in a cat nerve-muscle preparation is shown in Figure 10.6. Initially, there is a slight and transient facilitatory effect of succinylcholine on neuromuscular transmission; muscle twitch height momentarily increases by a small increment as a result of the initial depolarizing effect of the drug. Subsequently, however, muscle twitch rapidly decreases and within 1–2 minutes maximum depressant effect is obtained. Shortly thereafter, the neuromuscular effects of succinylcholine subside and muscle twitch returns to normal within an additional 5–8 minutes. The magnitude and duration of neuromuscular paralysis is dependent upon the dosage of succinylcholine. The relatively short duration of succinylcholine activity is from rapid biotransformation of this drug by plasma cholinesterase.

The effects of a cholinesterase inhibitor, neostigmine, on the neuromuscular paralysis produced by succinylcholine are demonstrated in Figure 10.6. By comparing the two tracings in this figure, it is apparent that neostigmine potentiated the muscle twitch depression evoked by succinylcholine and prolonged recovery from the effects of this agent. This synergistic interaction is primarily attributed to the anticholinesterase activity of neostigmine, resulting in decreased biotransformation of both succinylcholine and endogenous ACh. Thus succinylcholine and ACh are available at receptor sites for

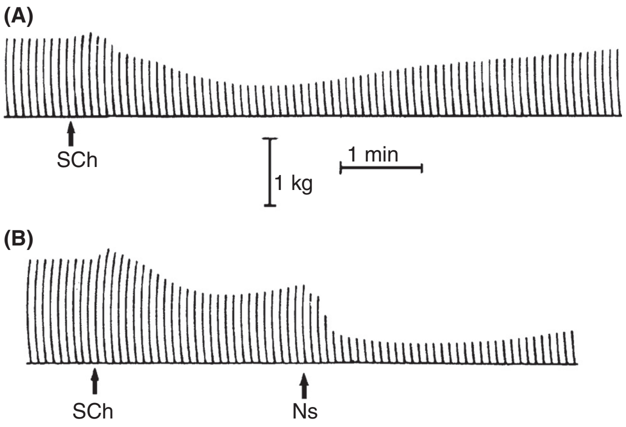

Figure 10.6 Neuromuscular blocking effect of succinylcholine (SCh) and augmentation of its effect by neostigmine (Ns) in a sciatic nerve-gastrocnemius muscle preparation of a cat. The cat was anesthetized with pentobarbital; muscle twitch was monitored as described in Figure 10.4. (**A**) Typical depression of muscle twitch by SCh (0.04 mg/kg) administered intravenously at designated arrow. (**B**) Augmentation of the muscle twitch depressant effect of SCh (0.04 mg/kg) by Ns (0.1 mg/kg). Agents were administered intravenously at designated arrows. Notice augmentation of the degree and duration of effect of SCh by Ns. Compare this with the antagonism by Ns of the neuromuscular blocking effect of *d*-tubo in Figure 10.5.

longer periods and the duration of depolarizing neuromuscular paralysis is prolonged.

The potency of neuromuscular effects of succinylcholine varies in different species (Hansson, 1958), as shown schematically in Figure 10.7, with bovine and canine species being quite sensitive to succinylcholine, whereas horses and pigs are considerably less responsive. This difference is probably dependent upon species differences in the activity of plasma cholinesterase, the enzyme that biotransforms succinylcholine (Radeleff and Woodard, 1956; Palmer et al., 1965). Cattle and sheep, for example, have considerably less detectable plasma cholinesterase activity than horses and pigs. Administration of purified cholinesterase preparation to dogs increases resistance to succinylcholine (Hall et al., 1953).

Autonomic Effects

Synaptic transmission at autonomic ganglia involves activation by ACh of nicotinic receptors of the postganglionic nerve body (see Chapter 8). It is not surprising, therefore, that NMB agents may also alter ganglionic transmission.

Tubocurarine is an excellent example of a drug selected for site of action at nicotinic receptors of the somatic myoneural junction that as a side effect also acts at ganglionic nicotinic receptors. Tubocurarine interacts with ganglionic receptors, renders them inaccessible to ACh, and thereby increases the threshold of the postganglionic nerve to ACh. However, as a general rule, autonomic ganglia are less sensitive to curare than are the myoneural junctions. Ganglionic impulse transmission involves, at least partially, a muscarinic pathway (see Chapter 7); *d*-tubocurarine has little blocking effect on muscarinic receptors. Thus in most cases it would be anticipated that ganglionic transmission is functional during treatment with curare-like drugs. Nevertheless, hypotension believed to be partly dependent upon ganglionic blockade can occur after administration of *d*-tubocurarine.

Other NMB drugs, both competitive and depolarizing types, have been shown experimentally to alter ganglionic transmission, but in clinically insignificant amounts. Succinylcholine induces transient ganglionic stimulation prior to blockade evoked by larger doses. The former effect may partially explain hypertension that has occurred subsequent to succinylcholine administration.

Parasympathetic effects of NMB agents are usually minimal. Succinylcholine is approximately 1,000 times less potent than ACh in eliciting contraction of guinea pig ileum. In dogs, large doses of succinylcholine induce

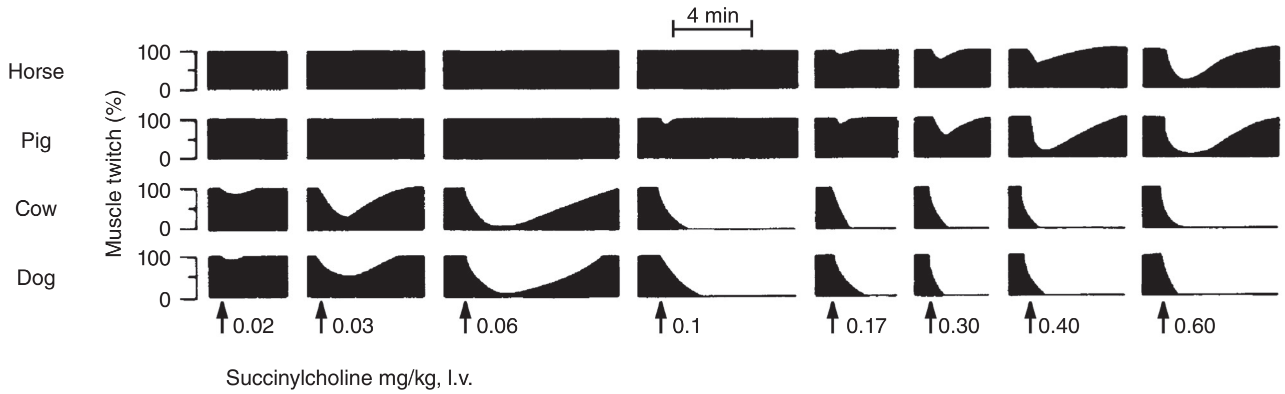

Figure 10.7 Schematic representations of the neuromuscular blocking effect of succinylcholine iodide in nerve-muscle preparations of different species during barbiturate anesthesia. Notice interspecies differences in degree and duration of paralysis caused by succinylcholine. Source: Modified from Hansson 1956, Lumb and Jones 1973.

salivation; this is antagonized by pretreatment with atropine (Hansson, 1956).

Histamine Release

d-Tubocurarine causes release of histamine. The magnitude of this response varies, depending on species, dosage, and rate and route of administration. Histamine-like wheals can be produced by subdermal and intraarterial administration of *d*-tubocurarine. In vivo, increased respiratory tract secretions and bronchospasm seen after administration of *d*-tubocurarine have been attributed to histamine release, as has the hypotensive effect of *d*-tubocurarine. Pretreatment with antihistamine drugs antagonizes these side effects; they are not inhibited by atropine or neostigmine. Succinylcholine and gallamine are very weak histamine-releasing agents.

Central Nervous System

Although synaptic transmission in the brain is altered by direct application of NMB drugs into the brain, CNS effects are nondetectable when these drugs are administered by other routes. NMB agents do not gain entry into the CNS to any appreciable extent because of the presence of the highly charged quaternary ammonium moieties. Therefore, neither CNS depression nor tranquilization is produced by NMB agents. Nonambulation results only from peripheral myoneural paralysis. This was decisively confirmed when Smith (Smith et al., 1947) allowed himself to be paralyzed with *d*-tubocurarine. At no time during the experiment did he experience hypnosis, tranquilization, amnesia, anesthesia, or analgesia. He simply could not voluntarily breathe or move, an experience described as quite frightful.

Cardiovascular Effects

As outlined above, *d*-tubocurarine often induces hypotension, particularly if rapidly administered to dogs. Slight increases in heart rate and cardiac output have been observed after administration of gallamine, apparently from a vagolytic effect on the heart (Longnecker et al., 1973). Others have reported no significant cardiovascular changes after IV administration of gallamine to anesthetized dogs (Evans et al., 1977). In cats, mild atropine-like effects on the heart were observed after injection of gallamine, pancuronium, and alcuronium (Hughes and Chapple, 1976).

Studies with pancuronium in humans and dogs indicated that this agent evokes slight increases in heart rate, blood pressure, and cardiac output during thiobarbiturate anesthesia (Coleman et al., 1972; Reitan and Warpinski, 1975). Cardiovascular effects of this agent were absent if patients were pretreated with atropine. Others have reported no significant cardiovascular changes with pancuronium (Brown et al., 1973). Similarly, studies have indicated that neither pancuronium nor gallamine significantly altered heart rate or blood pressure in anesthetized horses (Klein et al., 1983). Atracurium (up to 0.6 mg/kg) and vecuronium (up to 0.2 mg/kg) were reported to have negligible effects on arterial blood pressure in dogs (Jones, 1985a).

Succinylcholine usually evokes minimal cardiovascular changes in horses or dogs if administered during general anesthesia; blood pressure remains fairly constant if mechanical ventilation is provided (Evans et al., 1977; Benson et al., 1979).

Subparalytic doses of succinylcholine increase the arrhythmogenicity of epinephrine during light halothane anesthesia in dogs (Tucker and Munson, 1975). In dogs not treated with succinylcholine, an average dose of 4.15 μg/kg epinephrine was required to evoke premature ventricular contractions, whereas an average dose of 1.6 μg/kg epinephrine was the arrhythmogenic dose in dogs pretreated with 0.25 mg/kg succinylcholine. However, *d*-tubocurarine provides a slight protection against epinephrine-induced arrhythmias. Mechanisms involved in these drug interactions have not been clarified. If deemed essential, catecholamines should be used cautiously in patients treated with depolarizing NMB agents. Also, succinylcholine has been reported to increase susceptibility to the myocardial irritant effects of digitalis preparations, and it has been suggested that succinylcholine may be contraindicated in digitalized patients (Dowdy et al., 1965).

Pronounced cardiovascular side effects have been reported in horses after administration of succinylcholine (Larson et al., 1959; Hofmeyer, 1960; Lees and Tavernor, 1969). In general, these effects seem to be more pronounced in unanesthetized and unsedated animals than during general anesthesia. Severe hypertension, initial bradycardia followed by tachycardia, atrioventricular conduction disturbances, and extrasystoles have been reported, and myocardial damage has been suspected. Early institution of positive pressure ventilation has been reported to block the blood pressure effect. The hypertensive response seems to be at least partially mediated by the succinylcholine-induced dyspnea and the accompanying arterial $\mathrm{Po_2}$–$\mathrm{Pco_2}$ disturbances, causing a reflexogenic increase in blood pressure. Direct activation of autonomic ganglia by succinylcholine may also be involved.

It should be remembered that NMB agents do not depress the brain unless or until apnea-induced hypoxia actually causes syncope. Prior to hypoxic states, skeletal muscle paralysis affords no depression whatsoever of conscious centers of the brain of unanesthetized animals. It seems likely, then, that the novel sensations experienced by conscious animals as they are being paralyzed evoke profound fright. This can cause activation of autonomic centers within the brain. Autonomic discharge may be altered markedly resulting in cardiovascular side effects. Autonomic blockade has been shown to substantially decrease the cardiovascular side effects of succinylcholine, supporting the argument for its association with a stress response in those animals.

Ocular Effects

Clinically important ocular effects may occur as a result of pronounced contracture of ocular muscles that occurs after treatment with depolarizing neuromuscular blockers. These agents are contraindicated in glaucoma, since intraocular pressure may be increased. There is no contraindication for nondepolarizing NMB agents in this instance.

Serum Potassium

Depolarizing NMB agents cause a release of K^+ from skeletal muscle. This change is typically small in magnitude, but could be of concern in patients that already have an elevation in serum potassium. Elevation of serum K^+ may be particularly significant, if repeated injections of the NMB are given. There could be a greater risk in animals with muscle disorders, such as Golden Retriever muscular dystrophy (Larach, 1997).

Drug Interactions

Various drugs influence the pharmacological effects of muscle relaxants. NMB agents themselves alter activity of other neuromuscular agents. As would be expected, competitive agents summate with each other. Similarly, depolarizing agents also interact synergistically with one another. However, tubocurarine decreases the muscle twitch depressant effects of succinylcholine. This is related to persistent occupation of a certain portion of receptors by tubocurarine, although muscle twitch may have recovered (see Section Margin of Safety of Neuromuscular Transmission). Depolarization of the end-plate by succinylcholine is partially impeded by the stabilizing effects of tubocurarine. Succinylcholine antagonizes the effects of curare as a result of the partial agonistic characteristics of the former agent. These complex antagonistic interactions, however, have no clinical application, since they depend upon complicated treatment and time and dosage schedules. During clinical situations, NMB agents should not be used in attempts to reverse the effects of other types of NMB agents, since potentiation may occur despite experimental results to the contrary.

The interaction of cholinesterase inhibitors with NMB agents has been discussed in Section Skeletal Muscle. Cholinesterase inhibitors decrease responsiveness to the competitive agents, while they tend to increase intensity and duration of action of depolarizing agents (Sunew and Hicks, 1978). Organophosphate pesticides and anthelmintics, carbamates, and any other type of cholinesterase inhibitor will cause similar interactions.

Aminoglycoside antibiotics (neomycin, streptomycin, dihydrostreptomycin, kanamycin, gentamicin) decrease the release of ACh from the nerve and also the sensitivity of the end-plate to ACh (Pittinger and Adamson, 1972; Adams et al., 1976a). They do not cause depolarization. Their effects in many ways resemble those of low Ca^{++} or excess Mg^{++}. The presynaptic effect of antibiotics is believed to be due to interruption of Ca^{++} -dependent events at the axonal membrane (Adams, 1984). Cholinesterase inhibitors such as neostigmine antagonize the postsynaptic depressant effect of these antibiotics. Calcium antagonizes the presynaptic action and is usually more effective than neostigmine in reversing the neuromuscular paralyzing effects of aminoglycoside antibiotics. These antibiotics interact synergistically at the myoneural junction with NMB agents, anesthetics, and other antibiotics. The clinical significance of neuromuscular interactions of antibiotics and other drugs has been well established in humans and has been suggested in other species (Adams and Bingham, 1971). These subjects have been reviewed (Pittinger et al., 1970; Adams et al., 1976b; Keller et al., 1992).

Different disease states influence pharmacological effects of NMB agents. Hepatic synthesis of cholinesterase is decreased in the presence of liver disease. The duration of succinylcholine activity may be prolonged if the liver is seriously affected. Impairment of hepatic biotransformation may also cause prolongation of the effect of vecuronium. Renal dysfunction can delay excretion of *d*-tubocurarine, gallamine, doxacurium, and pancuronium.

Clinical Use

Muscle paralysis proceeds at different rates in different body regions after administration of a NMB agent. Usually, the extraocular muscles, the facial muscles, and those of the head and neck are affected first, often within 0.25–1 minute after injection. The tail is usually affected with the head and neck. Subsequently, muscles of the limbs are paralyzed, then the deglutition and laryngeal muscles (glottis). Abdominal muscles, intercostal muscles, and the diaphragm are then paralyzed in this order. Recovery usually proceeds in the reverse of this sequence (Hall, 1971).

Attempts have been made in clinical practice to use the sequential development of muscle paralysis by administering doses of NMB agents adequate to paralyze ambulatory muscle but insufficient to affect the diaphragm. This rarely has proven to be effective, because respiratory insufficiency may still occur, although the diaphragm is seemingly spared. Therefore, it is imperative that apparatus for administering mechanical ventilation be available when NMB agents are used clinically. To circumvent the need for immediate establishment of an adequate airway and other emergency procedures, it is wise to routinely perform tracheal intubation and institute ventilation whenever a NMB agent is used.

Muscle relaxants have been used in clinical practice for several purposes: to facilitate tracheal intubation; to paralyze respiratory muscles so that mechanical ventilation can be easily controlled; to increase muscle relaxation to facilitate surgical access to difficult anatomic regions; to evoke muscle relaxation to facilitate orthopedic manipulations or improve ocular positioning for surgery and as part of balanced anesthesia procedures to reduce the amount of general anesthetic required.

Tracheal intubation may be performed in a unanesthetized animal immediately after a paralyzing dose of NMB agent has taken effect. Prior administration of sufficient sedation or tranquilization is advisable for humane reasons and to circumvent potential side effects that may be precipitated by fear reaction to paralysis.

A wide range of dosages of NMB agents have been reported for use of these drugs during anesthesia (Hansson, 1956; Tavernor, 1971; Lumb and Jones, 1973). Often this variance reflects differences in the procedures reported in the original studies, for example, the use of different anesthetics and sedatives, different salts of the NMB agent, and in some cases the use of unanesthetized subjects. NMB agents should be given to effect rather than by bolus administration of a set precalculated dose. It is advisable for these drugs to be administered by titration during anesthesia and to be continuously correlated with the extent of muscle paralysis in the patient. The use of neuromuscular monitoring techniques markedly improves the ability to accurately dose and safely terminate the effects of neuromuscular blockade in all animals. Care should always be taken during the use of NMB agents to ensure that the animal does not suffer from residual paralysis as it enters the recovery period postanesthesia.

Margin of Safety of Neuromuscular Transmission

The concept of a margin of safety of neuromuscular transmission bears discussion in relation to clinical use of these drugs. It has been estimated that a relatively large percentage of the cholinergic receptors must be occupied by a paralyzing agent before muscle twitch fails. In the cat diaphragm, for example, muscle twitch is not affected until about 80% of the receptors are blocked by *d*-tubocurarine, and twitch is not completely abolished until about 90% of the receptors are occupied (Waud and Waud, 1972). Accordingly, for recovery of the diaphragm from the effects of a previous injection of *d*-tubocurarine, only a small percentage (5% in dogs, 18% in cats) of the receptors need to be free. Therefore, and most important, although to all outward signs recovery seems complete, over 80% of the receptors can still be blocked.

Recognition of this aspect becomes clinically important in the postoperative recovery room and should be considered in patients that have been exposed to NMB drugs and/or other myoneural depressants such as anesthetics. As a patient regains some control of voluntary muscles, spontaneous respiration returns and may seem completely normal. However, it must be remembered that at this time an extremely small margin of safety of neuromuscular transmission exists. That is, only a small percentage of the postsynaptic receptors are available for interaction with ACh; this small fraction of receptors is now responsible for maintaining muscle contraction. Therefore, if the patient is then exposed to another drug that as a side effect depresses neuromuscular function (even though it may be minimal or even nondetectable normally), disastrous complications may result. Anesthetic mortality has occurred in humans that can be attributed to such interactions. For example, Pridgen (1956) reported the anesthetic deaths of two children who were given neomycin immediately after completion of successful laparotomies under ether anesthesia. Initially, respiration was adequate, but within a short time after administration of the antibiotic, persistent apnea occurred. Death followed several hours later. It seems likely that the margin of safety of neuromuscular transmission was reduced in these infants by ether, resulting in marked augmentation of the neuromuscular blocking properties of neomycin. Pittinger et al. (1970) estimated a 9% death rate in human patients experiencing antibiotic-induced respiratory problems in conjunction with anesthetics and NMB agents. Apnea and eventual death in a traumatized dog were attributed to antibiotic (dihydrostreptomycin)-induced neuromuscular paralysis (Adams and Bingham, 1971).

These examples illustrate potential problems that may be inadvertently introduced in a patient that seemingly is recovering quite well from anesthesia and surgery. The margin of safety of neuromuscular transmission should be considered any time that anesthetics, NMB agents, or any other drug that depresses myoneural function are used in multiple drug regimens.

Clinical Reversal of Neuromuscular Paralysis

Treatment of persistent neuromuscular paralysis and/or treatment of inadvertent overdosage of NMB agents should be approached conservatively (Bevan et al., 1992).

The first step should be to initiate immediate (or to continue) positive pressure ventilation and to withdraw administration of the involved NMB agent. Often, ventilation will allow adequate time for the drug to be disposed of or metabolized by the patient's system. Exposure to other drugs that may synergistically interact with NMB agents should be avoided. However, if the effect of a neuromuscular blocker is no longer needed as the end of a procedure is approaching, reversal of the neuromuscular blockade from a nondepolarizing NMB agent is a good option. There are two classes of drugs used for reversal of neuromuscular blockade: the AChE inhibitors and the cyclodextrin, suggamedex (Jones et al., 2015).

Acetylcholinesterase Inhibitors

Acetylcholinesterase inhibitors, including edrophonium, neostigmine, and pyridostigmine, are available to reverse the action of nondepolarizing NMB drugs. As discussed in previous sections, AChE inhibitors are not routinely effective for the reversal of depolarizing NMB agents such as succinylcholine unless prolonged administration or repeat dosages have resulted in phase II block. Fortunately, recovery from succinylcholine is rapid and spontaneous because of plasma cholinesterases and the issue of drug reversal is rarely a clinical issue.

Acetylcholinesterase inhibitors act to inhibit the enzyme AChE thereby preventing the enzymatic hydrolysis of ACh into choline and acetic acid. This results in an increase in ACh that is not specific to the NMJ. While nicotinic effects occur at the NMJ and autonomic ganglia, muscarinic cholinergic effects also occur at the sinus node, smooth muscle, and glands. As nondepolarizing neuromuscular agents and ACh both compete for the same postsynaptic nicotinic receptor, an increase in ACh concentration in the synaptic cleft can tip the balance of competition in favor of ACh and neuromuscular transmission is restored.

Because of an increased ACh concentration at muscarinic cholinergic receptors, bradyarrhythmias, bronchoconstriction, nausea, vomiting, diarrhea, increased intestinal peristalsis, and salivation can adversely occur. In very rare incidences cardiopulmonary arrest has been reported. For this reason, anticholinergic drugs such as atropine or glycopyrrolate should always be available to treat excessive muscarinic side effects. Several human AChE inhibitor products come premixed with an anticholinergic and clinicians should confirm what product they have before drug administration. However, in veterinary medicine it is more common practice to administer an AChE inhibitor such as edrophonium and administer an anticholinergic drug only as needed based upon side effects observed.

Edrophonium, neostigmine, and pyridostigmine differ in how they inhibit AChE activity, in their onset and duration of action, and in their incidence of muscarinic side effects. Edrophonium is a prosthetic inhibitor that produces a reversible inhibition by electrostatic attachment to the anionic site and by hydrogen bonding at the esteratic site on AChE. Neostigmine and pyridostigmine are oxydiaphoretic (acid transferring) inhibitors and inhibit AChE by forming a carbamyl–ester complex at the esteratic site of AChE to form a covalent bond. Edrophonium has the most rapid onset of action followed by neostigmine and then pyridostigmine. The muscarinic effects of edrophonium are generally mild compared to neostigmine or pyridostigmine and for this reason edrophonium is the drug most commonly selected for neuromuscular blockade reversal in veterinary medicine. The duration of action is similar for both edrophonium and neostigmine, whereas pyridostigmine is approximately 40% longer (Cronnelly et al., 1982; Morris et al., 1981). Acetylcholinesterase inhibitors undergo hepatic biotransformation and renal elimination. Patients with renal disease may have prolonged drug elimination.

Larger doses of AChE inhibitors should antagonize nondepolarizing NMB drugs more rapidly and more completely than smaller doses do. In dogs, 0.5 mg/kg IV edrophonium reversed 100% of vecuronium treated dogs while subjects receiving only 0.25 mg/kg IV required further reversal (Clutton, 1994). Neostigmine can be administered to small and large animals by slow IV injection at the dose of 0.022 mg/kg. Atropine (0.01 mg/kg large animals; 0.04 mg/kg small animals) should be administered prior to or in conjunction with neostigmine to circumvent the muscarinic effects of the latter drug (Klein et al., 1983; Jones et al., 2015).

While both metabolic and respiratory acidemia may augment the blockade induced by a nondepolarizing neuromuscular blocker, only respiratory acidemia inhibits drug reversal. Therefore, the effectiveness of AChE inhibitors may be reduced if a patient hypoventilates (Miller et al., 1974; Miller et al., 1978). Calcium channel blockers such as verapamil have been shown to potentiate nondepolarizing NMB drugs and may make achieving adequate reversal more difficult (Wali, 1986; Jones et al., 1985).

Sugammadex

Sugammadex (Org 25969) is a unique agent recently available to reverse the effects of nondepolarizing NMB agents. It is the first drug to be known as a selective relaxant binding agent (SRBA). Sugammadex is a modified γ-cyclodextran that when administered, tightly encapsulates aminosteroid-based nondepolarizing NMB agents. The cyclodextran structure has a hydrophobic cavity and a hydrophilic exterior because of the presence of polar hydroxyl groups. Hydrophobic interactions trap the NMB agent tightly in the cyclodextrin cavity and form a water-soluble guest–host complex which is readily available for elimination. This creates a concentration gradient favoring movement of the remaining nondepolarizing NMB agent away from the NMJ and its site of action and into the plasma.

Sugammadex appears to be most effective in reversal of rocuronium, followed by vecuronium, and then pancuronium. Administered at a dose of 2–8 mg/kg IV in man, the drug appears to have excellent efficacy in the face of deep neuromuscular blockade when traditional reversal with AChE inhibitors might fail. Additionally, as sugammadex does not increase the presence of ACh, it is devoid of muscarinic signs and appears to be largely free of side effects. In phase I and II trials, the most frequently reported side effects were hypotension, coughing, nausea, and xerostomia. Although cost and widespread availability have yet to make the drug's use commonplace, sugammadex has been evaluated in dogs and appears to offer promising clinical benefit. In dogs undergoing profound neuromuscular blockade with rocuronium or vecuronium, an 8 mg/kg IV dose of sugammadex results in a restoration of a TOF ratio to 0.9 in under 2 minutes with no adverse side effects.

Neostigmine or other cholinesterase inhibitors should not be used in attempts to reverse the effects of a depolarizing agent (Sunew and Hicks, 1978). Reliable chemical antidotes are not available for this group of agents. Mechanical ventilation may be required for a prolonged period. Injection of purified cholinesterase preparation has been shown to hasten recovery from the effects of succinylcholine (Scholler et al., 1977).

Because of the small therapeutic index of NMB agents, their clinical use should always be supervised by qualified experienced personnel who are thoroughly familiar with the indications, limitations, hazards, and methods of administration of these highly active drugs.

Inhalation Anesthetics

Robert J. Brosnan and Eugene P. Steffey

Inhalation anesthetics are unique among the anesthetic drugs because they are administered, and in large part removed from the body, via the lungs. They are used widely for the anesthetic management of animals in part because their pharmacokinetic characteristics favor predictable and rapid adjustment of anesthetic depth. In addition, a special apparatus is usually used to deliver the inhaled agents. This helps minimize patient morbidity or mortality because it facilitates accurate and controlled anesthetic delivery, lung ventilation, and improved arterial oxygenation. Partial pressures of modern agents also rapidly equilibrate between the lung alveoli and active sites within the central nervous system (CNS). Breath-by-breath monitoring of end-tidal (alveolar) anesthetic concentrations can be routinely monitored by agent analyzers that, in effect, allow indirect breath-by-breath monitoring of drug partial pressures within CNS sites responsible for anesthetic action.

Over the nearly 170 years that inhalation anesthesia has been used in clinical practice, fewer than 20 agents have actually been introduced and approved for general use with patients. Fewer than 10 of these have had any history of widespread clinical use in veterinary medicine, and only four are currently of major clinical importance in North America (Table 11.1). All are relatively old agents, the most recent – sevoflurane – having been first synthesized and studied in the 1970s (Terrell, 2008). However, the reason for this apparent lack of drug innovation is not because the ideal inhalation anesthetic has already been identified. An ideal agent would have characteristics that include a stable shelf life without preservatives and compatibility with existing delivery equipment. It would be inexpensive to purchase, nonflammable, and easily vaporized under ambient conditions and have a high boiling point. Such an agent would have a low blood solubility to foster rapid changes in anesthetic depth and permit rapid, controlled recovery from anesthesia. The ideal agent would exhibit potency sufficient to produce surgical anesthetic planes at concentrations less than 50–60% of one atmosphere partial pressure. There would be no cardiopulmonary depression or cardiac sensitization to arrhythmias; the agent would not be irritating to airways and would have a pleasant odor (or be odorless). The drug would not lower seizure threshold, would not cause neuronal injury, and would provide analgesia (or at least not cause hyperalgesia). Finally, it would produce good skeletal muscle relaxation, resist degradation in the anesthetic delivery apparatus, undergo no biotransformation, be nontoxic to the kidneys and liver, and not cause emesis. No inhalation agent in current use fulfills all of these criteria.

Physiochemical Characteristics

The chemical structure of inhalation anesthetics and their physical properties are important to their actions and determine how these drugs are administered, what delivery and scavenge equipment is required, which techniques can be used to monitor vapor concentrations in patients, and whether or how these agents are metabolized.

Chemical Characteristics

A large number of structurally disparate agents have been delivered by inhalation to produce general anesthesia, including single atom elements (Lawrence et al., 1946a; Koblin et al., 1998), diatomic elements (Koblin et al., 1998), oxides of carbon (Thompson, 1912; Brosnan et al., 2007) and nitrogen (Wells, 1847), cyclic alkanes (Waters and Schmidt, 1934), unhalogenated (Taheri et al., 1993; Liu et al., 1994) and halogenated (Snow, 1858; Suckling, 1957; Whalen et al., 2005) n-alkanes, unhalogenated (Riggs, 1925) and halogenated (Hewer, 1942; Dingman and Lim, 1963) alkenes, unhalogenated (Jackson and Morton, 1847; Krantz et al., 1946) and halogenated (Artusio et al., 1960; Terrell, 2008) ethers, among others. With the exception of the inorganic compound nitrous oxide (N_2O), contemporary anesthetics in common use are either halogenated ethers or a halogenated alkane (Figure 11.1). Halogenation renders modern

organic anesthetics nonflammable at clinically relevant concentrations.

Physical Characteristics

Clinical administration of inhalation anesthetics requires a carrier gas that must include oxygen, a source of anesthetic, and a patient breathing circuit. For very small animals (e.g., laboratory rodents or small birds) this may mean nothing more than placing the animal in a closed air-filled chamber that contains a cotton pledget saturated with liquid anesthetic (e.g., isoflurane). With larger animals and/or to provide more controlled delivery of anesthetic and O_2, it is more appropriate to use a specialized delivery apparatus to improves the safety and control of anesthetic concentrations delivered to patients. The anesthetic machine includes one or more flow meters, one or more vaporizers, and a patient breathing circuit. Reviews of vaporizers and other anesthetic delivery equipment are available elsewhere (Dorsch and Dorsch, 2007; Tranquilli et al., 2007; Miller et al., 2014).

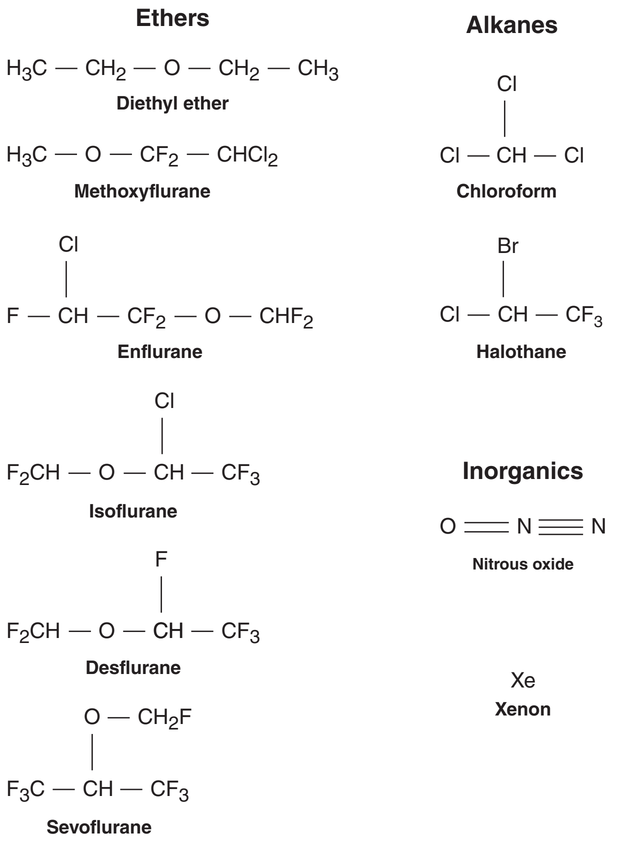

Figure 11.1 Chemical structures of inhalation anesthetics of clinical (halothane, methoxyflurane, enflurane, isoflurane, sevoflurane, desflurane), investigational (xenon), and historical (diethyl ether, chloroform) interest.

Gas versus Vapor

Inhalation anesthetics are either gases or vapors. N_2O exists as a gas under operating room conditions because at 1 atmosphere pressure, the boiling point of N_2O is −89°C. Consequently, N_2O for clinical use in tanks is compressed to the liquid state at about 750 psi (pounds per square inch; 750 psi/14.9 psi [1 atmosphere] = 50 atmospheres). As the N_2O gas is drawn from the tank, liquid N_2O is vaporized, and the overriding gas pressure remains constant until no further liquid remains in the tank. At that point, only N_2O gas remains, and the gas pressure decreases from this point as remaining gas is vented from the tank.

The term "vapor" indicates the gaseous state of a substance that at ambient temperature and pressure is a liquid; volatile anesthetics have sufficient vapor pressure to be administered via inhalation. The volatile agent desflurane has a boiling point of 23.5°C (Table 11.2); it boils (becomes a gas) only slightly above typical 20°C ambient room temperature or at altitudes higher than 1100 meters (3600 feet) due to decreased barometric pressure. As a result, a specialized vaporizer is required to maintain temperature and pressure constant and allow for precise and safe delivery of this agent.

Methods of Description

Quantities of inhalation anesthetic agent are usually characterized by one of three methods: pressure (e.g., in mmHg), concentration (in volumes %), or mass (in mg or g). The form most familiar to clinicians is that of concentration (e.g., *X*% of agent A in relation to the whole gas mixture). Modern monitoring equipment samples inspired and expired gases and provides concentration readings for inhalation anesthetics. Precision vaporizers used to control delivery of inhalation anesthetics are calibrated in percentage of agent, and effective doses are almost always reported in percentages. Finally, the molecular weight and agent density are used in ideal gas calculations to convert from liquid to vapor volumes and mass (Hill, 1980).

Table 11.2 Some physiochemical properties of volatile anesthetics. Source: Data from Lerman et al., 1983; Taheri et al., 1991; Soares et al., 2012.

Property	Desflurane	Halothane	Isoflurane	Sevoflurane	Enflurane	Methoxyflurane
Molecular weight	168	197	185	200	185	165
Liquid specific gravity (20°C) (g/ml)	1.47	1.86	1.49	1.52	1.52	1.42
Boiling point(°C)	23.5	50	49	59	57	105
Vapor pressure						
20°C (68°F)	664	244	240	160	172	23
24°C (75°F)	798	288	286	188	207	28
ml of vapor/mL of liquid at 20°C	209.7	227	195	183	198	207
Partition coefficients

olive oil/gas (37°C)	19.2	224	98.9	51.3	103	611

Vapor Pressure

The vapor pressure of an anesthetic is an indicator of its ability to evaporate; it reflects the tendency for molecules in the liquid state to enter the gaseous (vapor) form. The vapor pressure of a potent volatile anesthetic must be sufficient to provide enough molecules of anesthetic in the vapor state to produce anesthesia at ambient conditions. The *saturated vapor pressure* represents a maximum concentration of molecules in the vapor state that can exist for a given liquid at each temperature. The *saturated vapor concentration* can be easily determined by relating the vapor pressure to the ambient pressure. Using halothane and associated information from Table 11.2 as an example, we see that a maximal concentration of 32% halothane is possible under usual operating-room conditions; that is, $244/760 \times 100 = 32\%$, where 244 mmHg is the vapor pressure at 20°C and 760 mmHg is the barometric pressure at sea level. Thus, other variables considered constant, the greater the vapor pressure, the greater the concentration of the drug deliverable to the patient.

Properties Influencing Drug Kinetics: Solubility

As described by Henry's Law, the partial pressure exerted by a concentration of gas in solution is inversely proportional to the solubility of that gas in that solvent. The solubility of an anesthetic is a major characteristic of the agent and has important clinical ramifications. For example, anesthetic solubility in blood and body tissues is a primary factor in the rate of uptake and distribution within the body. It is therefore a primary determinant of the speed of anesthetic induction and recovery. Solubility in lipid bears a strong relationship to anesthetic potency, and the tendency to dissolve in anesthetic delivery components such as rubber influences equipment selection and other aspects of anesthetic management.

The extent to which a gas will dissolve in a given solvent is usually expressed in terms of its *partition coefficient* (PC)(Table 11.3), a distribution constant that describes the concentration ratio of a gas between two bulk phases (e.g., between blood and gas) at a specified temperature. It thus describes the affinity or capacity or solubility of an anesthetic for one solvent phase relative to another, that is, how the anesthetic will *partition* itself between two phases after equilibrium has been reached. Anesthetic gas movement occurs because of a partial pressure difference in the two phases so that when there is no longer any anesthetic partial pressure difference between the two phases, there is no longer any net movement of anesthetic in either phase direction, and equilibrium has been achieved. Solvent/gas and human tissue/gas PCs are summarized in Table 11.3; some of these differ significantly from values in animals for some agents (Soares et al., 2012).

Table 11.3 Partition coefficients at 37°C. Source: Data from Eger, 1981; Goto et al., 1998; Lynch et al., 2000; Eger et al., 2003a.

Agent	Blood/gas	Oil/gas	Brain/blood	Heart/blood	Liver/blood	Kidney/blood	Muscle/blood	Fat/blood
Desflurane	0.45	19	1.2	1.2	1.5	0.9	1.7	29
N_2O	0.46	1.4	1.1	1.0	–	–	1.2	2.4
Sevoflurane	0.65	47	1.7	1.7	2.0	1.2	2.6	52
Isoflurane	1.4	98	1.6	1.6	1.9	1.0	2.6	50
Enflurane	2.0	96	1.4	–	1.9	1.0	1.1	42
Halothane	2.4	224	1.9	1.7	2.3	1.3	2.9	57
Methoxyflurane	15	970	1.3	–	1.9	0.7	1.0	60
Xenon	0.12	1.8	1.6	–	–	0.9	0.9	–

Of all the PCs that have been described or are of possible interest, two are of particular importance in the practical understanding of anesthetic management. They are the blood/gas and the oil/gas partition coefficients.

Blood/Gas Partition Coefficient

The blood/gas solubility (Table 11.3) is a determinant of the speed of anesthetic onset (induction or change in anesthetic level) and offset (recovery). All else being equal, a lower blood/gas PC allows for more rapid anesthetic induction or rate of change of anesthetic level in response to a stepwise change in anesthetic delivery.

Oil/Gas Partition Coefficient

The oil/gas PC is another solubility characteristic of clinical importance (Table 11.3). This PC describes the ratio of concentration of an anesthetic in oil (in this case olive oil is the generally agreed upon standard) and gas phases at equilibrium. The oil/gas PC correlates inversely with anesthetic potency and describes the capacity of lipids for anesthetic.

Other Partition Coefficients

Solubility characteristics for tissues (Table 11.3) and other media like rubber and plastic (components of anesthetic delivery equipment; Table 11.4) are also important. For example, tissue solubility determines in part the quantity of anesthetic removed from the blood to which it is exposed. The higher the tissue solubility, the more anesthetic is removed from the blood, which slows the rate of rise of anesthetic partial pressure at active sites. During recovery, anesthetic can leave these tissue reservoirs and oppose anesthetic washout and delay recovery time. High agent solubility in rubber (Table 11.4) will oppose the rise of anesthetic partial pressure within the anesthetic apparatus (such as in an equine anesthetic circuit that often uses a substantial quantity of rubber in hoses and breathing bags) and slow anesthetic delivery to the patient.

Table 11.4 Rubber or plastic/gas partition coefficients at room temperature. Source: Data from Marx et al., 1996; Eger et al., 2003a.

Agent	Latex Rubber	Silicone Rubber	Polyvinyl chloride	Polyethylene
Desflurane	19	–	35	16
N_2O	1.2	–	–	–
Sevoflurane	29	–	68	31
Isoflurane	49	67	110	2
Enflurane	74	–	120	2
Halothane	190	165	190	26
Methoxyflurane	630	–	–	118

Pharmacokinetics: Uptake and Elimination of Inhalation Anesthetics

The aim in administering an inhalation anesthetic to a patient is to achieve partial pressure or tension of anesthetic (P_{anes}) in the CNS to achieve a desired level of anesthesia. Movement of molecules of inhalation anesthetics, like O_2 and CO_2, occurs down partial pressure gradients (Figure 11.2). Gases move from regions of higher tension to those of lower tension until equilibrium (i.e., equal partial pressure in the two media) is established. Anesthetic partial pressure is highest immediately downstream from the vaporizer and is progressively less as gas travels to a semiclosed anesthetic breathing circuit, from circuit to lungs, from lungs to arterial blood, and, finally, from arterial blood to body tissues such as the brain and spinal cord (Figure 11.2). With modern drugs, the anesthetic partial pressure in the pulmonary alveoli rapidly equilibrates the anesthetic partial pressure in highly vascular tissues receiving large arterial blood flow (such as sites of anesthetic action within the CNS). Hence, the alveolar partial pressure (P_A) of anesthetic is in a delayed

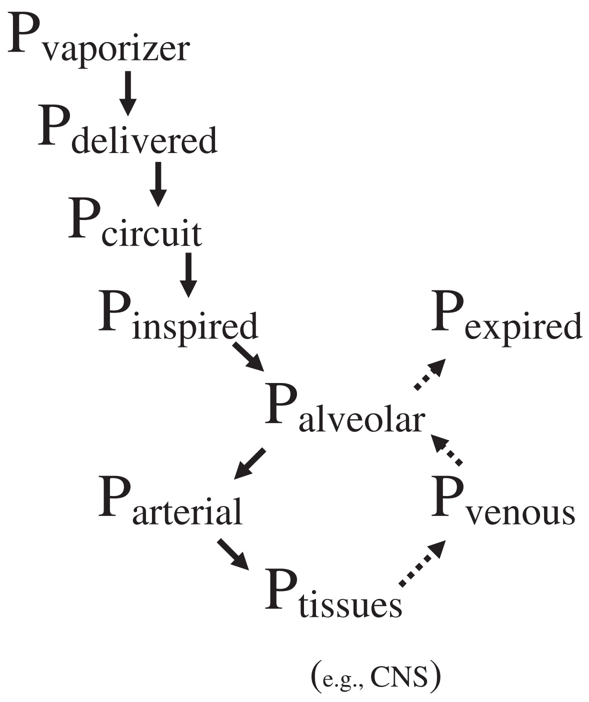

Figure 11.2 The movement of inhaled anesthetic agents down a series of partial pressure gradients (gas tension gradients) during induction and recovery. During induction there is a high anesthetic tension in the vaporizer that decreases progressively towards the site of action in the CNS.

Table 11.5 Factors that promote a rapid change in alveolar anesthetic tension

- A. Increased alveolar delivery of anesthetic
  - 1. Increased inspired anesthetic concentration
    - a. Increased vaporization of agent
    - b. Increased vaporizer dial setting
    - c. Increased anesthetic-laden fresh gas inflow to the patient breathing circuit
    - d. Decreased gas volume of patient breathing circuit
    - e. Vaporizer positioned in a patient rebreathing circuit
  - 2. Increased alveolar ventilation
    - a. Increased minute ventilation
    - b. Decreased ventilation of respiratory system dead space
- B. Decreased removal of anesthetic from the alveoli
  - 1. Decreased blood solubility of anesthetic
  - 2. Decreased cardiac output
  - 3. Decreased alveolar–venous anesthetic gradient

equilibrium with the CNS partial pressure of anesthetic. Monitoring drug alveolar partial pressure allows indirect real-time monitoring of the effect site concentration.

The P_A of anesthetic is a balance between anesthetic input (i.e., delivery to the alveoli) and loss (uptake by blood and body tissues) from the lungs (Figure 11.2). A rapid rise in P_A of anesthetic is associated with a rapid anesthetic induction or change in anesthetic depth. Factors that contribute to a rapid change in P_A of anesthetic are summarized in Table 11.5.

Delivery to the Alveoli

Delivery of anesthetic to the alveoli – and the rate of rise of the alveolar concentration or fraction (F_A) toward the inspired concentration or fraction (F_I) – depends on the inspired anesthetic concentration itself and the magnitude of alveolar ventilation. Increasing either one of these or both increases the rate of rise of the P_A of anesthetic.

Inspired Concentration

The upper limit of inspired concentration is dictated by the agent vapor pressure at a given temperature. Characteristics of the patient breathing system are also important, including the type of circuit (open, semiopen, semiclosed, or closed), the amount of rubber or plastic in the system, the position of the vaporizer relative to the breathing circuit (i.e., within or outside the circuit), and the fresh gas inflow to the patient breathing circuit (Eger, 1974; Dorsch and Dorsch, 2007; Tranquilli et al., 2007; Brosnan, 2013; Miller et al., 2014).

Alveolar Ventilation

An increase in alveolar ventilation increases the rate of delivery of inhalation anesthetic to the alveoli. If unopposed, alveolar ventilation would rapidly increase the alveolar concentration of anesthetic so that within minutes the alveolar concentration would equal the inspired concentration. However, in reality, the input created by alveolar ventilation is initially diluted by the volume of the lung's functional residual capacity (FRC) and subsequently by absorption of anesthetic into blood. Hypoventilation reduces the rate at which the alveolar concentration increases over time compared to the inspired concentration.

Removal from Alveoli: Uptake by Blood

Anesthetic uptake is the product of three factors: solubility (S; the blood/gas solubility, Table 11.3), cardiac output (CO), and the difference in the anesthetic partial pressure between the alveoli and venous blood returning to the lungs ($P_A{-}P_v$; expressed in mmHg); that is,

$$\text{Uptake} = \text{S} \times \text{CO} \times [(P_A - P_v)/P_{bar}]$$

where P_{bar} = barometric pressure in mmHg (Eger, 1974). Note that if any of these three factors equals zero, there is no further uptake of anesthetic by blood.

Solubility

The solubility of an inhalation anesthetic in blood and tissues is characterized by its partition coefficient (PC; Table 11.3). Compared to an anesthetic agent with high blood solubility (PC), an agent with low blood solubility should be associated with a more rapid equilibration between tissue phases because a large amount of the highly soluble anesthetic must be dissolved in the blood before equilibrium is reached with the gas phase. In the case of the agent with a high blood/gas PC, the blood acts like a large "sink" into which the anesthetic is poured, and thus a large blood anesthetic concentration is required before a large blood anesthetic partial pressure can be reached. It is the partial pressure gradient, and not the concentration gradient, that determines diffusion of gases. As a result, it takes more soluble anesthetics more time to reach a given blood partial pressure and CNS partial pressure than less soluble anesthetics. Anesthetic agents with a low blood/gas PC are desirable because they permit: (i) a more rapid anesthetic induction (i.e., more rapid rate of rise in alveolar concentration during induction; Figure 11.3); (ii) more precise control of anesthetic depth (i.e., alveolar concentration during the anesthetic maintenance phase of anesthesia); and (iii) a more rapid elimination of anesthetic and recovery from anesthesia (i.e., a rapid decrease in alveolar concentration during the anesthetic recovery phase).

Cardiac Output

Cardiac output, the amount of blood flowing through the lungs (or systemic circulation) per unit time, influences anesthetic uptake from the lungs. With greater cardiac output, there is a greater quantity of blood passing through the lungs that will take up anesthetic from the

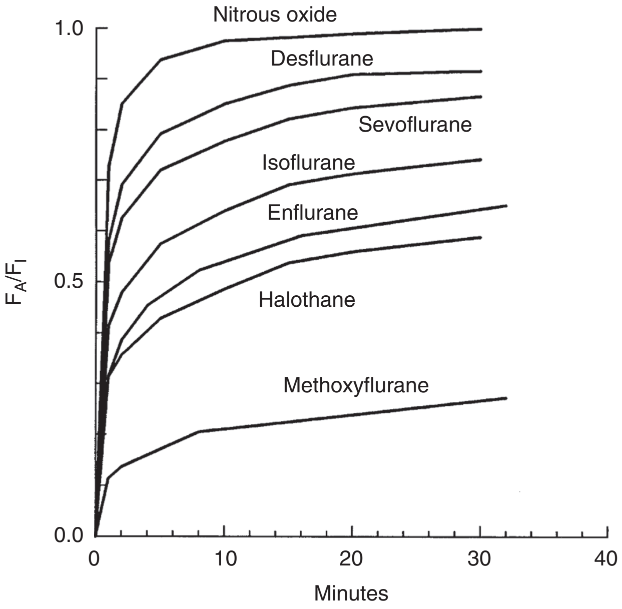

Figure 11.3 The rise in the alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration in humans. Note the rise is most rapid with the least soluble anesthetic, N_2O, and slowest with the most soluble anesthetic, methoxyflurane. Source: Data from Eger and Eger, 1985; Eger, 1992.

alveoli. A large CO, like increased anesthetic agent blood solubility, delays the alveolar rise of P_{anes} and anesthetic onset.

Alveolar to Venous Anesthetic Partial Pressure Difference

The magnitude of difference in anesthetic partial pressure between the alveoli and venous blood is related to the amount of uptake of anesthetic agent by tissues. Not surprisingly, the largest gradient occurs during induction. Once the tissues no longer absorb anesthetic (i.e., equilibrium between the two phases is reached), there is no longer any uptake of anesthetic agent from the lungs; the venous blood returning to the lungs contains as much agent as when it left the lungs. The changes in gradient in between these extremes result from the relative distribution of CO. In this regard it is important to recognize that roughly 70–80% of the CO is normally directed to only a small volume of body tissues in a lean individual (Table 11.6) (Eger, 1974; Staddon et al., 1979; Yasuda et al., 1990; Eger and Saidman, 2005). Tissues such as brain, heart, hepatoportal system, and kidneys represent only about 10% of the body mass but normally receive about 75% of the total blood flow each minute. These highly perfused tissues equilibrate relatively rapidly with the arterial anesthetic tension. Since the venous anesthetic tension equals that in the tissue within 10–15 minutes, about 75% of the blood returning to the lungs is the same as the alveolar tension, presuming that arterial anesthetic tension is held constant. Thus anesthetic uptake is reduced over time. Skin and muscle compose the major bulk of the body (about 50% in humans) but at rest receive only about 15–20% of the CO, so saturation of this tissue group may require up to a few hours to accomplish. Fat is a variable component of body bulk and receives only a small proportion of blood flow. Consequently, anesthetic saturation of this tissue group is very slow, especially given that all anesthetics are considerably more soluble in fat than in other tissue groups (Table 11.3).

Table 11.6 Blood flow characteristics in different tissue groups. Source: Eger, 1974. Reproduced with permission of El Eger.

	Tissue group[a]			
	Vessel rich	Muscle	Fat	Vessel poor
% of body mass	10	50	20	20
% of cardiac output	75	19	5	<1

[a] Brain, heart, hepatoportal, kidney are examples of components of the "vessel rich" grouping and ligaments, tendons, bone are examples within the "vessel poor" tissue grouping.

Other factors can further influence the magnitude of the alveolar-to-arterial anesthetic partial pressure gradient. They include body size (Wahrenbrock et al., 1974), abnormalities of lung ventilation/perfusion (Eger and Severinghaus, 1964), loss of anesthetic via the skin (Stoelting and Eger, 1969b; Fassoulaki et al., 1991; Lockhart et al., 1991b) and into closed gas spaces (Eger, 1974; Eger, 1985; Eger et al., 2003a), and metabolism (Eger, 1974; Eger et al., 2002; Eger et al., 2003a).

Anesthetic Recovery

Recovery from inhalation anesthesia is a consequence of anesthetic elimination from the CNS. This first requires washout of anesthetic from the alveoli and blood (Figure 11.2). Factors favoring a faster rate of rise of CNS anesthetic partial pressure are the same factors that favor faster anesthetic elimination: alveolar ventilation, CO, and the agent blood/gas partition coefficient. Indeed, graphs representing anesthetic wash-out from the alveoli versus time (Figure 11.4) are essentially inverse of the anesthetic wash-in curves (Figure 11.3).

Anesthetic elimination kinetics also exhibit context sensitivity with respect to time; drug washout is slower as the duration of anesthesia increases. The relative context sensitivity increases as a function of the agent solubility in blood and body tissues (Eger and Johnson, 1987; Eger, 1993; Eger et al., 1998; Eger and Saidman, 2005; Eger and Shafer, 2005). During anesthetic maintenance, agent concentrations gradually increase in less perfused muscle and viscera and, more slowly, in fat. These large tissue volumes become an ever increasing reservoir of anesthetic until their partial pressure equilibrates with that

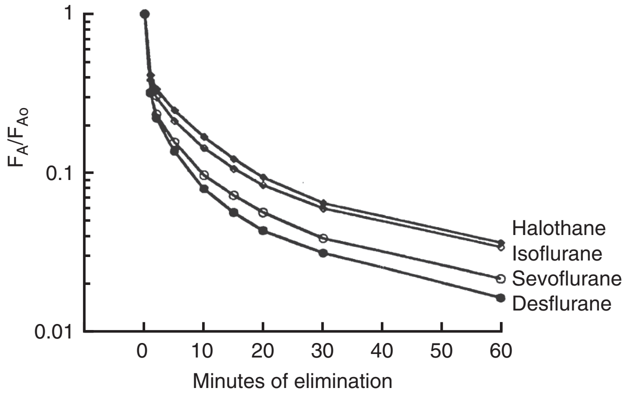

Figure 11.4 The fall in alveolar (F_A) concentration relative to the alveolar concentration at the end of anesthesia (F_{A0}). Note that the newest, most insoluble volatile anesthetic, desflurane, is eliminated in humans more rapidly than the other contemporary potent anesthetics. Not shown is information for methoxyflurane; if present the curve for methoxyflurane would appear above that for halothane. Source: Eger, 1992. Reproduced with permission of Wolters Kluwer Health.

of the arterial blood. During recovery, gradual anesthetic washout from less vascular tissues can oppose the fall in anesthetic partial pressure in the blood and redistribute to the CNS, thereby delaying anesthetic recovery.

Other factors contributing to anesthetic elimination from the body include percutaneous loss (Stoelting and Eger, 1969b; Cullen and Eger, 1972; Fassoulaki et al., 1991; Lockhart et al., 1991b), intratissue (Neumann et al., 2005) or intertissue (Carpenter et al., 1986b; Carpenter et al., 1987) diffusion of agents, and body size and composition (Lemmens et al., 2008). Metabolism plays a small role with some older inhalation anesthetic agents, such as methoxyflurane or halothane (Cahalan et al., 1981; Carpenter et al., 1986a; Carpenter et al., 1987), but not with newer volatile agents which are largely eliminated unchanged by the respiratory system.

Anesthetic Dose: The Minimum Alveolar Concentration

The standard index of potency for inhalation anesthetics is the minimum alveolar concentration (MAC) (Merkel and Eger, 1963; Eger et al., 1965; Eger, 2002), the alveolar concentration of an inhaled anesthetic that prevents gross nonreflexive movement in 50% of subjects exposed to a supramaximal noxious stimulus. Thus, MAC is equivalent to the median effective dose, or ED_{50}, for inhaled anesthetics. The dose that corresponds to the ED_{95} (95% of the individuals are anesthetized), at least in humans, is 20–40% greater than MAC (de Jong and Eger, 1975); and 2.0 times the MAC (i.e., 2 MAC) represents a deep level of anesthesia, in some cases even an anesthetic overdose. MAC values for contemporary inhalation anesthetics in select animal species are summarized in Table 11.7.

Table 11.7 The minimum alveolar concentration (MAC) of inhalation anesthetics. Source: Data from Lynch et al., 2000; Steffey and Mama, 2007.

Anesthetic	Cat	Dog	Horse	Human
Methoxyflurane	0.23	0.29	0.28	0.16
Halothane	1.04	0.87	0.88	0.74
Isoflurane	1.63	1.30	1.31	1.15
Enflurane	2.37	2.06	2.12	1.68
Sevoflurane	2.58	2.36	2.31	2.05
Desflurane	9.79	7.20	8.06	7.25
Xenon	–	119	–	71
Nitrous oxide	255	222	205	104

The anesthetic potency of an inhaled anesthetic is inversely related to MAC (i.e., potency = 1/MAC). MAC of conventional anesthetics is inversely related to the oil/gas PC, as described by the Meyer–Overton relationship (Figure 11.5) (Meyer, 1899; Overton, 1991). Thus, a very potent anesthetic (e.g., methoxyflurane) has a low MAC value and a high oil/gas PC; an agent of low anesthetic potency (e.g., N_2O) has a high MAC and a low oil/gas PC.

It is important to note that MAC is normally determined in healthy animals under controlled laboratory conditions in the *absence* of other drugs and other circumstances common to clinical use that may modify anesthetic requirements. Many factors may either increase or decrease MAC (anesthetic requirement). The interested reader is referred elsewhere for reviews of this topic (Stoelting and Hillier, 2006; Tranquilli et al., 2007; Miller et al., 2014).

Pharmacodynamics: Actions and Toxicity of the Inhalation Anesthetics

By virtue of their effects on multiple cellular targets, inhaled anesthetics have widely distributed and largely depressant effects on function of most body systems. Though the magnitude of some actions vary with agent, the effect profile of most potent modern alkane and ether type anesthetics is remarkably similar. In contrast, the less potent inorganic anesthetics (N_2O and Xe) may not produce similar anesthetic endpoints and side effects in all species at standard pressures. Following is an overview of major inhalation anesthetic effects on body systems with a focus on drug effects in healthy patients. However, the reader is cautioned that effects both desirable (e.g., immobilization potency) and adverse (e.g., cardiorespiratory depression) may be modified by a number of variables encountered in clinical and laboratory settings,

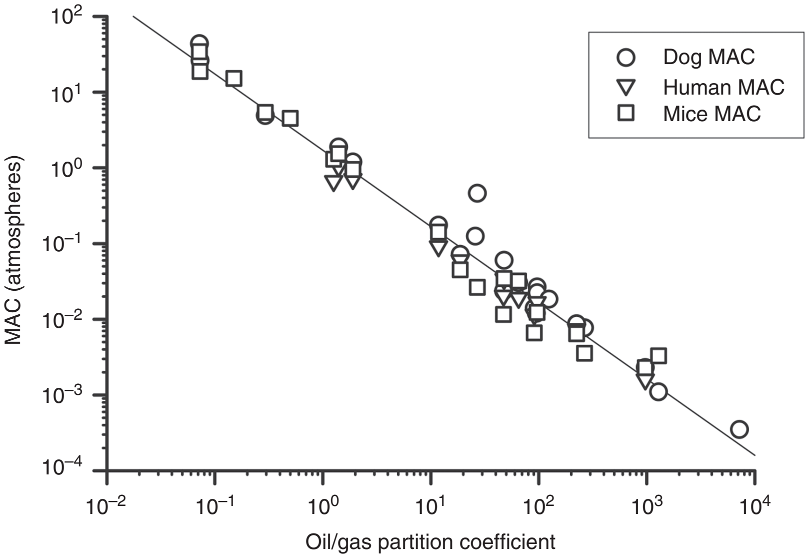

Figure 11.5 Oil/gas partition coefficients versus potency (MAC) of inhalation anesthetics in dogs, humans and mice. Source: Miller et al., 2014. Reproduced with permission of Elsevier.

including species, genetics, duration of anesthesia, noxious (surgical) stimulation, ventilation mode, coexisting disease, and concurrent medications. We refer the reader to additional references that discuss these interactions in greater detail (Tranquilli et al., 2007; Miller et al., 2014).

Central Nervous System

Inhalation anesthetics produce a reversible generalized CNS depression for which the degree of depression is often described as depth of anesthesia. The components of general anesthesia have traditionally been considered to include: unconsciousness, amnesia, analgesia, and immobility. Some also include in this concept, suppression of autonomic reflexes. Most recently, in attempting to better define the site(s) and mechanism(s) of action of inhalation anesthetics this list has been distilled to just two reversible qualities applying to all inhalation agents: amnesia and immobility in response to a noxious stimulus (Eger et al., 2003a; Eger and Sonner, 2006).

The inhaled agents cause immobility and amnesia, but these distinct endpoints are achieved via actions at different CNS sites. In an experimental goat model in which the cerebral circulation was isolated from the rest of the body, selective brain isoflurane administration more than doubled the anesthetic requirement for immobility compared to whole-body isoflurane administration. This demonstrated that the spinal cord, and not the brain, is principally responsible for preventing movement during surgery with inhaled anesthetics (Antognini and Schwartz, 1993). Within the spinal cord, immobility is most likely produced by depression of locomotor neuronal networks located in the ventral horn (Jinks et al., 2005).

In contrast, amnestic effects of inhaled anesthetics are produced by actions within the brain, most probably within the amygdala and hippocampus (Eger et al., 2003b). Lesions created within the amygdala of rats can block amnestic actions of sevoflurane (Alkire and Nathan, 2005). On electroencephalography, hippocampal-dependent θ-rhythm frequency slows in proportion to the amnestic effects observed with subanesthetic concentrations of isoflurane in rats (Perouansky et al., 2010). Furthermore, mutant mice lacking the gene encoding either the α_4 or β_3 subunits of $GABA_A$ receptors are resistant to isoflurane depression of hippocampus-dependent learning and memory (Rau et al., 2009; Rau et al., 2011), and antagonism of α_5 subunit-containing $GABA_A$ receptors restores hippocampal-dependent memory during sevoflurane administration (Zurek et al., 2012). Clearly the mechanisms of inhaled anesthetic action responsible for amnesia are different from those responsible for immobility.

At concentrations above MAC, it is presumed that inhaled anesthetics sufficiently depress cortical function to prevent animals from experiencing motivational-affective dimensions of pain (Melzack and Casey, 1967). Additionally, concentrations of modern volatile agents (halothane, enflurane, isoflurane, sevoflurane, desflurane) between 0.8 and 1.0 times MAC decrease (but do not ablate) wind-up and central sensitization and so may help prevent heightened postoperative pain sensitivity; however, higher concentrations of contemporary drugs offer no further benefit in this regard (O'Connor and Abram, 1995; Mitsuyo et al., 2006). Volatile anesthetic concentrations between 0.4 and 0.8 times MAC decrease withdrawal responses to noxious stimuli, but lower concentrations can actually cause hyperalgesia with a peak effect at 0.1 times MAC (Sonner et al., 1998; Zhang et al., 2000) due to potent nicotinic cholinergic receptor inhibition (Flood et al., 2002). In contrast, the gaseous anesthetics xenon and nitrous oxide produce analgesia via glutamatergic receptor inhibition (Yamakura and Harris, 2000), and in the case of nitrous oxide, through additional modulation of noradrenergic–opioid receptor pathways (Zhang et al., 1999). Anatomically, analgesic actions occur both supraspinally and within the dorsal horn of the spinal cord, and are likely responsible for greater blunting of autonomic responses associated with these gases as compared to the modern volatile agents (Nakata et al., 1999).

Unconsciousness, at least insofar as it may be correlated with loss of the righting reflex and spontaneous movement (Quasha et al., 1980), may occur at yet other sites within the CNS. Nicotine injections into the central medial thalamus causes partial-to-full arousal in rats lightly anesthetized with sevoflurane, suggesting a role of nicotinic acetylcholine receptors within this region (Alkire et al., 2007). Within the midbrain, electrical stimulation (Solt et al., 2014) or injection of D_1 receptor agonists (Taylor et al., 2013) into the ventral tegmental area reverses the immobilizing effects of isoflurane in rats, thus indicating a role for dopamine receptors. Presumably, thalamic and brainstem arousal allows subsequent activation of other cortical regions responsible for information processing and integration, a hallmark of consciousness (Tononi, 2008).

Of the contemporary inhaled anesthetics, enflurane (Joas et al., 1971; Neigh et al., 1971) and sevoflurane (Adachi et al., 1992; Komatsu et al., 1994; Osawa et al., 1994; Woodforth et al., 1997; Hilty and Drummond, 2000) are capable of producing epileptiform activity during electroencephalography. However, tonic–clonic muscle activity is typically only observed with enflurane, whereas sevoflurane may actually raise the threshold for seizure manifestation (Karasawa, 1991; Fukuda et al., 1996; Murao et al., 2000a), although perhaps less so than other inhaled agents (Murao et al., 2002). Isoflurane (Koblin et al., 1981; Fukuda et al., 1996; Murao et al., 2000a, 2000b) and desflurane (Fang et al., 1997b) suppress convulsive activity induced by such drugs as bupivacaine, lidocaine, and penicillin.

Inhalation anesthetics are cerebral vasodilators and tend to increase cerebral blood flow and interfere with normal cerebral vascular autoregulation. These effects are agent dependent (less with sevoflurane) (Conzen et al., 1992; Gupta et al., 1997; Matta et al., 1999; Nishiyama et al., 1999; Summors et al., 1999; Bedforth et al., 2000), dose dependent (less at sub-MAC concentrations) (Bundgaard et al., 1998; Matta et al., 1999; Werner et al., 2005), and species dependent (autoregulation better preserved in horses than humans and small animals) (Brosnan et al., 2011). Cerebrovasodilation increases intracranial blood volume and pressure, resulting in increased intracranial pressure that is exacerbated by head-down body positioning (Brosnan et al., 2002a, 2002b), hypercapnia (Brosnan et al., 2003a, 2003b), prolonged anesthetic duration (Brosnan et al., 2003a), and pathophysiological changes associated with increased intracranial elastance (Brosnan et al., 2004), such as intracranial masses, hemorrhage, edema, and hydrocephalus (North and Reilly, 1990). Severe and uncompensated increases in intracranial pressure can cause cerebral herniation and also decrease the extracranial-to-intracranial pressure gradient, defined as the cerebral perfusion pressure, resulting in cerebral ischemia.

In the adult, inhaled anesthetic preconditioning offers some degree of neuroprotection during subsequent hypoxic or ischemic insults (Xiong et al., 2003; Kehl et al., 2004; Zheng and Zuo, 2004; Payne et al., 2005; Li et al., 2008; Li and Zuo, 2009; Yang et al., 2011). However, in neonates, many inhaled agents can adversely affect neural viability or neural development. Contemporary volatile anesthetics have been associated with neuronal apoptosis in the brains and spinal cords of neonatal rats (Sanders et al., 2008b; Istaphanous et al., 2011) and monkeys (Brambrink et al., 2010, 2012); the longer-term clinical consequences for behavioral changes or learning and memory deficits are presently unresolved (Jevtovic-Todorovic et al., 2003b; Culley et al., 2004; Loepke et al., 2009; Satomoto et al., 2009; Kodama et al., 2011). In the aged, inhaled agents have been associated with postanesthetic cognitive dysfunction (Culley et al., 2003; Zhang et al., 2012) with the suggestion that impairment could be secondary to accumulation of amyloid protein within the brain (Xie et al., 2006). Although important in animals, implications of these potential side effects are even greater for humans.

Respiratory System

All contemporary inhalation anesthetics depress alveolar ventilation. As a consequence, the P_aCO_2 is increased in direct relation to anesthetic dose (MAC multiple; Figure 11.6). The magnitude of P_aCO_2 is also species related (Figure 11.7). In addition, the normal stimulation to ventilation caused by an increased P_aCO_2 and/or a low arterial oxygen tension (P_aO_2) is reduced (Knill and Gelb, 1978; Knill et al., 1983; Dahan et al., 1994, 1996; Sarton et al., 1996; Sjogren et al., 1998, 1999; Miller et al., 2014).

Bronchospasm is associated with some diseases and other patient conditions and contributes to increased airway resistance. Among the earlier available volatile anesthetics, halothane was the most effective bronchodilator (Klide and Aviado, 1967; Coon and Kampine, 1975). Subsequent work with isoflurane, sevoflurane, and desflurane indicates the relaxation of constricted bronchial muscles by these agents is equal to or exceeds that caused by halothane (Hirshman and Bergman, 1978; Mazzeo et al., 1996; Rooke et al., 1997; Habre et al., 2001; Dikmen et al., 2003), although very deep anesthetic planes (≥2

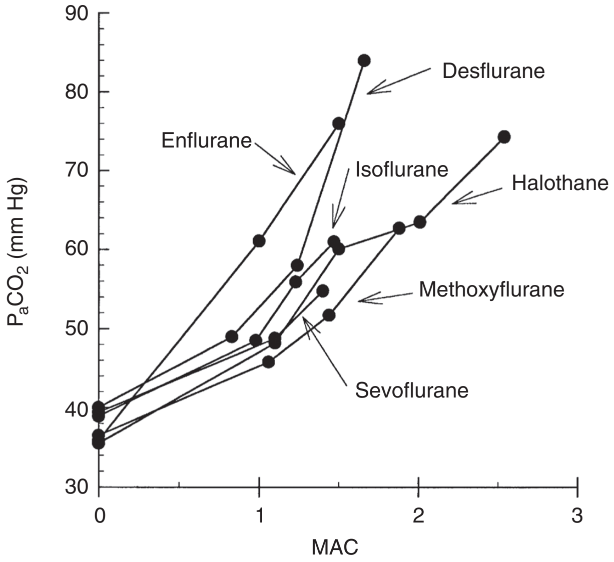

Figure 11.6 A summary of the effects of contemporary volatile anesthetics on P_aCO_2 in humans. Source: Data from Munson et al., 1966; Larson et al., 1969; Calverley et al., 1978; Doi and Ikeda, 1987a; Lockhart et al., 1991a.

times MAC) of desflurane may be associated with loss of bronchodilation, possibly due to release of tachykinin (Dikmen et al., 2003; Nyktari et al., 2006; Satoh et al., 2009).

Volatile inhalation anesthetics may inhibit reflex hypoxic pulmonary vasoconstriction and thereby contribute to a maldistribution of ventilation to perfusion and an increase in the alveolar-to-arterial partial pressure of oxygen and decrease in P_aO_2 (Marshall et al., 1984; Miller et al., 2014). However, results of in vivo studies of clinically relevant concentrations of volatile anesthetics suggest minimal or no inhibitory effects (Mathers et al., 1977; Fargas-Babjak and Forrest, 1979; Domino et al., 1986; Lesitsky et al., 1998; Kerbaul et al., 2000, 2001).

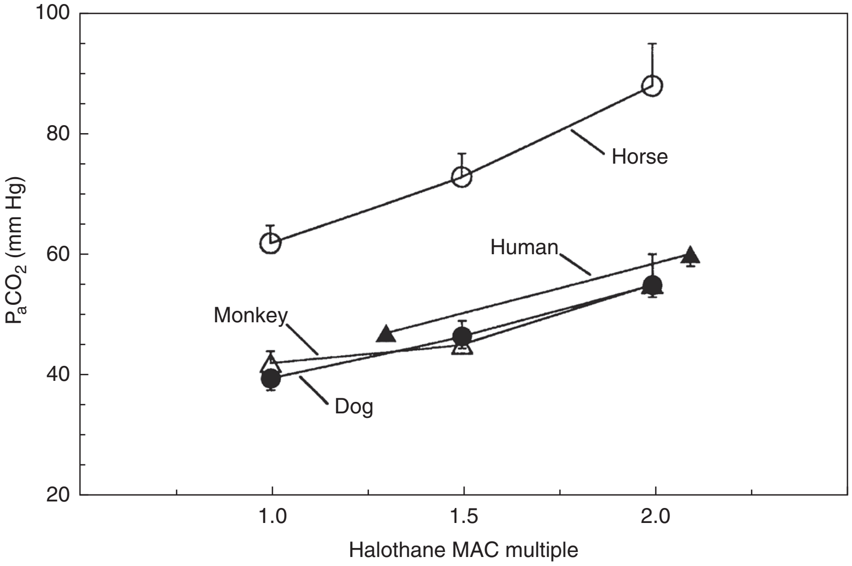
Airway irritation caused by inspiring an inhalation anesthetic is undesirable. Airway irritation has not been generally recognized as a problem associated with induction of anesthesia in animals. However, human patients commonly react by breath holding, coughing, and laryngospasm when exposed to concentrations of 7% or more desflurane early in the course of anesthesia (Eger, 1993; TerRiet et al., 2000). As a result, desflurane is not commonly used for anesthetic induction in human patients.

Cardiovascular System

Inhalation anesthetics may produce drug specific and/or dose-related effect. Such effects may manifest as changes in arterial blood pressure, cardiac output, stroke volume, heart rate, and/or rhythm of heart beat. Such changes may be caused by effects on myocardial contractility, peripheral vascular smooth muscle, and/or autonomic nervous system tone. Effects imposed by inhalation anesthetics may be further impacted by controlled versus spontaneous ventilation, concurrently administered drugs with direct or indirect hemodynamic actions, and preexisting cardiovascular disease.

All of the volatile anesthetics decrease cardiac output, usually via a decrease in myocardial contractility (Eger, 1981; Eisele, 1985; Pagel et al., 1991b; Boban et al., 1992; Warltier and Pagel, 1992; Pagel et al., 1993) and, in turn, stroke volume. The magnitude of change is dose related and dependent on the agent (Klide, 1976; Steffey and Howland, 1978a, 1980; Eger, 1981; Merin et al., 1991; Warltier and Pagel, 1992; Mutoh et al., 1997; Hanouz et al., 2000). Arterial blood pressure is also decreased in a dose-related manner (Figure 11.8) (Steffey et al., 1974b,

Figure 11.7 The P_aCO_2 (mean ± SE; mm Hg) in spontaneously breathing, health dogs, horses, humans and monkeys during halothane-oxygen anesthesia. The anesthetic dose is expressed as a multiple of the minimum alveolar concentration (MAC) for each species. Source: Steffey, 2009.



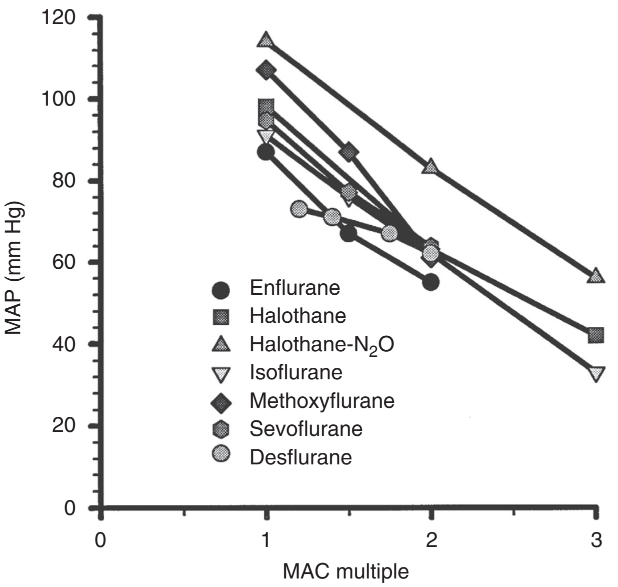


Figure 11.8 Inhalation anesthetics dose-dependently (expressed as multiples of MAC) decrease mean arterial blood pressure (MAP) in mechanically-ventilated normocapnic dogs. Source: Data from Steffey et al., 1975; Steffey and Howland, 1978a; Steffey et al., 1984; Merin et al., 1991; Frink et al., 1992b.

1974c; Steffey and Howland, 1977; Merin et al., 1991; Frink et al., 1992b; Mutoh et al., 1997). The decrease in arterial blood pressure is usually related to a decrease in cardiac output and a decrease in peripheral vascular resistance, the relative contributions of which varies between species.

All volatile anesthetics depress myocardial contractility via alterations of intracellular calcium homeostasis at several subcellular locations in normal cardiac muscle (Bosnjak et al., 1991; Davies et al., 2000; Huneke et al., 2001; Park et al., 2007). The rank order of depression of contractile function is halothane = enflurane > isoflurane = desflurane = sevoflurane (Miller et al., 2014). Volatile anesthetics can provide important beneficial effects on mechanical function during myocardial ischemia and myocardial reperfusion injury. For a more complete review of mechanisms of action of volatile anesthetics on myocardial function readers are referred to the recent review by Pagel and colleagues (Miller et al., 2014).

Inhalation anesthesia may alter the normal distribution of blood flow to organs. Specific effects are agent, dose, and time related (Vatner and Smith, 1974; Manohar and Parks, 1984a, 1984b; Manohar and Goetz, 1985; Bernard et al., 1991; Merin et al., 1991; Hartman et al., 1992; Eger et al., 2003a). For example, while volatile anesthetics cause a dose-dependent increase in cerebral blood flow, similar circumstances may decrease blood flow to the liver and kidneys (Gelman et al., 1984a, 1984b; Miller et al., 2014). Temporal changes in cardiovascular function have also been reported in a variety of animals during inhalation anesthesia (Vatner and Smith, 1974; Dunlop et al., 1987; Steffey et al., 1987a, 1987b, 1987c, 1987d).

Cardiac Rhythm and Catecholamines

Inhalation anesthetics may increase the automaticity of the myocardium (Price, 1966). This effect is exaggerated by adrenergic agonists (Katz and Epstein, 1968). N-alkane anesthetics such as halothane sensitize the heart to arrhythmogenic effects of catecholamines (Raventos, 1956; Joas and Stevens, 1971; Munson and Tucker, 1975; Johnston et al., 1976; Eger, 1981; Weiskopf et al., 1989; Moore et al., 1993; Navarro et al., 1994; Miller et al., 2014); this side effect is not apparent with conventional ether agents.

Liver

Hepatocellular injury may result as a general consequence of a reduction in hepatic blood flow or by direct volatile anesthetic agent toxicity. The chlorinated methanes, including chloroform, remain a classic research model for induction of hepatic injury (Plaa, 2000). However, of the contemporary volatile agents, liver injury is occasionally reported with halothane (Pohl et al., 1989; Kenna and Jones, 1995). Newer ether-type anesthetics have much less pronounced effects on hepatic blood flow (Merin et al., 1991; Bernard et al., 1992; Crawford et al., 1992; Frink et al., 1992b; Hartman et al., 1992), and isoflurane and desflurane undergo comparatively trivial biotransformation (Holaday et al., 1975; Ghantous et al., 1991; Njoku et al., 1997; Eger et al., 2002).

Gastrointestinal

Although inhaled agents are commonly associated with postanesthetic nausea and vomiting in people, emesis in the recovery period appears uncommon in most domestic animals.

Kidneys

All of the volatile anesthetics reduce renal blood flow and glomerular filtration rate in a dose-related manner (Mazze et al., 1974; Cousins et al., 1976). Decreased urine output during inhalation anesthesia may be a consequence of decreased renal perfusion, but it can also be associated with extracellular fluid accumulation caused by the inhaled anesthetics (Brauer et al., 2002; Connolly et al., 2003; Weiss and Pizov, 2003). A transient increase in serum urea nitrogen, creatinine, and inorganic phosphate also may accompany inhalation anesthesia, especially if prolonged (Steffey et al., 1979, 2005a, 2005b;

Steffey and Howland, 1980; Eger, 1981). In most cases the effects of inhalation anesthesia on renal function are rapidly reversed after anesthesia. Beyond these general responses, methoxyflurane is notable with regard to its potential for causing nephrotoxicity (Mazze et al., 1971, 2006).

Skeletal Muscle

The volatile anesthetics are associated with some small amount of skeletal muscle relaxation, likely a direct result of their CNS depression and depressant calcium channel effects. They also enhance the muscle relaxation induced by the nondepolarizing neuromuscular blocking drugs that are sometimes used as adjuvants in the anesthetic management of patients.

Malignant hyperthermia is life-threatening pharmacogenetic myopathy involving a defect of the ryanodine (or sometimes dihydropyridine) receptor in the sarcoplasmic reticulum (Lanner et al., 2010; Hopkins, 2011; Bannister and Beam, 2013). It is most commonly found in certain pig breeds (Landrace, Pietrain, Poland China, Yorkshire, and Duroc) and in certain human familial lines (Fujii et al., 1991), although genetic mutations associated with the disease have been reported in other domestic species including dogs (Short and Paddleford, 1973; Roberts et al., 2001) and horses (Aleman et al., 2004, 2005). While historically associated with halothane anesthesia (Denborough et al., 1962), all of the modern volatile agents including enflurane (McGrath et al., 1981), isoflurane (McGrath et al., 1981; Boheler et al., 1982), sevoflurane (Shulman et al., 1981), and desflurane (Wedel et al., 1991) can trigger malignant hyperthermia in susceptible individuals. In contrast, nitrous oxide has little or no malignant hyperthermia-triggering effect (Reed and Strobel, 1978; McGrath et al., 1981).

Unless confirmed otherwise, animals related to individuals with known or suspected malignant hyperthermia, including pigs derived from herds reporting the presence of porcine stress syndrome or pale soft exudative pork, are themselves at risk for malignant hyperthermia and should be managed accordingly. The resultant syndrome of malignant hyperthermia is characterized by muscle rigidity, a rapid rise in body temperature, large consumption of oxygen, and consequent production of CO_2. Death rapidly ensues in many cases unless very aggressive therapy is instituted. No volatile anesthetics should be administered in these patients, and anesthetic machines potentially leaching trace vapors should either be avoided or activated carbon filters be used to prevent breathing of triggering agents (Birgenheier et al., 2011). Dantrolene (Harrison, 1975) or azumolene (Dershwitz and Sreter, 1990) are the treatments of choice for a fulminant malignant hyperthermia episode.

Actions by Agent

Additional actions by agent will be highlighted in this section. The volatile agents will be reviewed first, with an emphasis on the most common contemporary ether-type anesthetics: isoflurane, desflurane, and sevoflurane. Because of their limited or declining use in research or clinical practice, methoxyflurane, enflurane, and halothane will be discussed only with respect to major advantages or disadvantages compared to the three haloether anesthetics in greatest contemporary use. Additional information about these older agents and others, such as diethyl ether and chloroform, can be found in previous editions of this textbook. Finally, the gaseous agent, N_2O, will be discussed. Although approaching many of the goals of an “ideal” inhaled anesthetic, xenon remains too scarce and expensive for clinical use in veterinary patients. The interested reader is encouraged to consult other references regarding xenon pharmacology (Lawrence et al., 1946b; Lynch et al., 2000; Sanders et al., 2003; Preckel and Schlack, 2005; Bovill, 2008; Giacalone et al., 2013).

Isoflurane

Isoflurane USP (Forane, Aerrane, IsoFlo, Attane), is a halogenated methyl ethyl ether and a structural isomer of enflurane. It is a racemic mixture of 2-chloro-2-(difluoromethoxy)-1, 1, 1-trifluoro-ethane.

Isoflurane was first synthesized in 1965, and its widespread clinical use for human patients began in 1981. At least in North America, it is now the most widely used volatile anesthetic agent in veterinary patients.

CO_2 Absorbent Stability

Isoflurane is degraded by Baralyme, and to a lesser extent by soda lime containing monovalent bases, to produce carbon monoxide. The magnitude of this breakdown is increased by desiccated absorbent and by high concentrations of the volatile agent (Fang et al., 1995). CO_2 absorbents lacking sodium hydroxide or potassium hydroxide cause negligible breakdown of isoflurane (Murray et al., 1999; Stabernack et al., 2000).

Biotransformation

In humans and animals isoflurane resists biodegradation. In humans less than 0.2% of the isoflurane taken up by the body is metabolized (Holaday et al., 1975); this rate of metabolism is far less than for enflurane or sevoflurane (Table 11.8). Both inorganic fluoride and trifluoroacetic acid have been identified as end products of isoflurane metabolism (Njoku et al., 1997), but serum concentrations are small even after prolonged isoflurane administration due to minimal metabolism (Cousins et al., 1973; Dobkin et al., 1973; Mazze et al., 1974). Isoflurane also

Table 11.8 Biotransformation of inhalation anesthetics in humans

Anesthetic	Metabolized (%)	Reference
Methoxyflurane	50	Holaday et al., 1970
Halothane	20–25	Rehder et al., 1967; Cascorbi et al., 1970
Sevoflurane	3	Eger, 1994
Enflurane	2.4	Chase et al., 1971
Isoflurane	0.17	Holaday et al., 1975
Desflurane	0.02	Eger, 1994
Nitrous oxide	0.004	Hong et al., 1980

does not appear to be a mutagen, teratogen, or carcinogen (Eger et al., 1978; Eger, 1981).

Central Nervous System

Isoflurane, unlike its isomer enflurane, has anticonvulsant effects(Koblin et al., 1981). Electrical silence is seen on the EEG at 2 MAC (Clark and Rosner, 1973). However, cats given isoflurane display “sharp waves” (isolated spiking) on the electroencephalogram (EEG). This activity is also seen in cats with halothane, enflurane, and methoxyflurane and may be a species peculiarity (Julien and Kavan, 1974; Kavan and Julien, 1974).

Cardiovascular System

Isoflurane depresses cardiovascular function in a dose-related fashion (Steffey and Howland, 1977; Steffey et al., 1977, 1987a; Eger, 1981; Ludders et al., 1989) that is modified in magnitude by anesthetic duration (Dunlop et al., 1987; Steffey et al., 1987c). The magnitude of its effect on arterial blood pressure is similar to halothane, although with isoflurane the cause is more related to a decrease in the systemic vascular resistance. Also like halothane, it decreases cardiac contractility and stroke volume, resulting in a decrease in cardiac output. However, results of studies in a number of species indicate that isoflurane, especially at light and moderate levels, affects cardiac output less than halothane does. Isoflurane thus offers a wider margin of safety compared to halothane.

Heart rate tends to be better maintained during isoflurane and remains relatively constant over a range of alveolar isoflurane doses. Heart rhythm is usually little affected by isoflurane, and the incidence of dysrhythmias after injection of vasoactive substances (including catecholamines) is substantially reduced in comparison to halothane (Joas and Stevens, 1971; Tucker et al., 1974; Johnston et al., 1976; Bednarski et al., 1985).

Respiratory System

Isoflurane depresses respiration and increases P_aCO_2 (Steffey and Howland, 1977, 1980; Steffey et al., 1977; Eger, 1981; Miller et al., 2014). The magnitude of depression is dose and time related and is at least equal to or often greater than that caused by halothane under similar conditions (Cromwell et al., 1971; Steffey and Howland, 1977; Eger, 1981; Steffey et al., 1987c; Brosnan et al., 2003b; Miller et al., 2014). In some species, like the horse, during light and moderate levels of anesthesia respiration is characterized by large tidal volume and low breathing rate (Steffey et al., 1977; Brosnan et al., 2003b).

The alveolar concentration that causes apnea is 2.5 MAC for the dog (Steffey and Howland, 1977) and 2.3 MAC for the horse (Steffey et al., 1977).

Desflurane

Desflurane USP (Suprane), formerly known as I-653, is a polyfluorinated methyl-ethyl ether. It is a racemic mixture of 2-(difluoromethoxy)-1,1,1,2-tetrafluoro-ethane.

Although first synthesized in the 1960s along with similar agents such as enflurane and isoflurane, desflurane was not actively investigated for clinical use at that time because it was difficult to produce and had a boiling point only slightly above room temperature (Eger, 1993). Its first reported use in humans was in 1990 (Jones et al., 1990a, 1990b).

Desflurane has a high vapor pressure (Table 11.2) and requires temperature-controlled, pressurized vaporizer for predictable delivery (Andrews et al., 1993). It has a very low solubility in blood (Table 11.3) (Eger, 1987; Soares et al., 2012), and other tissues (Yasuda et al., 1989), contributing to greater precision of control over the maintenance of anesthesia and a very rapid emergence from anesthesia (Eger and Johnson, 1987; Yasuda et al., 1989, 1990, 1991; Jones et al., 1990a; Barter et al., 2004; Steffey et al., 2005b, 2009).

CO_2 Absorbent Stability

Desflurane is degraded by Baralyme or soda lime containing monovalent bases to produce carbon monoxide. The magnitude of this breakdown is increased by desiccated absorbent and by high concentrations of the volatile agent (Fang et al., 1995). CO_2 absorbents lacking sodium hydroxide or potassium hydroxide cause negligible breakdown of desflurane (Murray et al., 1999; Stabernack et al., 2000; Coppens et al., 2006).

Biotransformation

Desflurane resists degradation by the body to a greater degree than any of the other volatile anesthetics (Koblin et al., 1988; Jones et al., 1990c; Koblin, 1992); actual amounts of degradation are too small to measure accurately. Direct renal toxicity has not been reported, direct hepatic toxicity caused by trifluoroacetylation of liver proteins is rare (Njoku et al., 1997; Anderson et al., 2007).

Central Nervous System

Desflurane is less potent than other contemporary volatile agents (Table 11.7). For example, MAC for the dog, horse, and pig is 7.2%, 8.1%, and 10.0%, respectively (Doorley et al., 1988; Eger et al., 1988; Steffey et al., 2005b).

Desflurane causes dose-related depression of EEG activity comparable to effects seen with an equipotent dose of isoflurane (Rampil et al., 1988, 1991). Epileptiform EEG activity is not reported.

Cardiovascular System

The cardiovascular actions of desflurane are similar to those of isoflurane (Weiskopf et al., 1988, 1989, 1991; Pagel et al., 1991b; Warltier and Pagel, 1992; Clarke et al., 1996; McMurphy and Hodgson, 1996; Santos et al., 2005; Steffey et al., 2005b). Like isoflurane and halothane, desflurane decreases mean arterial blood pressure and stroke volume in dose-related fashion. But cardiac output during desflurane, as with isoflurane, is better maintained compared to conditions during halothane anesthesia. Heart rate is usually higher and peripheral vascular resistance less with desflurane compared to the other volatile agents (Pagel et al., 1991a). As with other agents, myocardial contractility is depressed in a dose-dependent manner (Pagel et al., 1991b; Boban et al., 1992). However, initial uptake of desflurane can be associated with increased sympathetic tone, resulting in transient increases in heart rate and blood pressure (Ebert and Muzi, 1993; Weiskopf et al., 1994). Desflurane does not predispose the heart to ventricular arrhythmias, nor does it sensitize it to arrhythmogenic effects of epinephrine (Weiskopf et al., 1989; Moore et al., 1993).

Respiratory System

Desflurane, like other contemporary volatile anesthetics, causes a dose-related respiratory depression (Lockhart et al., 1991a; McMurphy and Hodgson, 1996; Santos et al., 2005; Souza et al., 2005; Steffey et al., 2005b). Its effects in this regard in humans are most comparable to those of enflurane (i.e., more depressing than isoflurane). Apnea occurs in pigs at alveolar desflurane concentrations between 1.2 and 1.6 MAC, while the apneic threshold in dogs is 2.38 MAC (Warltier and Pagel, 1992).

Sevoflurane

Sevoflurane USP (Ultane, Sevoflo), a polyfluorinated methyl-isopropyl ether, was synthesized in the early 1970s, and its characteristics were first described in 1975 (Wallin et al., 1975). It is 1, 1, 1, 3, 3, 3-hexafluoro-2-(fluoromethoxy)-propane which lacks a chiral center. Because sevoflurane was difficult and expensive to synthesize at the time and was known to be degradable, it was not introduced until the late 1980s – first in Japan (Doi and Ikeda, 1987b; Katoh and Ikeda, 1987) and then in the USA in 1995 (Callan, 2012). Sevoflurane formulations containing low concentrations of water may be subject to Lewis-acid degradation in some vaporizers, resulting in formation of hydrofluoric acid (Kharasch et al., 2009).

The blood solubility of sevoflurane is less than isoflurane but, in most species, is greater than desflurane (Wallin et al., 1975; Strum and Eger, 1987; Soares et al., 2012). Compared to other inhaled agents, sevoflurane provides a relatively rapid anesthetic induction and anesthetic recovery (Wallin et al., 1975; Sarner et al., 1995; Hikasa et al., 1996; Johnson et al., 1998).

CO_2 Absorbent Stability

As with other modern ether-type anesthetics, sevoflurane is capable of producing small amounts of carbon monoxide when exposed to Baralyme or older soda lime formulations containing monovalent bases. However, these absorbents also cause sevoflurane breakdown into 1, 1, 3, 3, 3-pentafluoro-2-(fluoromethoxy)-1-propene, also known as compound A (Wallin et al., 1975; Strum et al., 1987; Liu et al., 1991; Frink et al., 1992a), a nephrotoxin that is lethal in 50% of rats (LD_{50}) at a concentration of 400 ppm (Hikasa et al., 1996). In addition, sevoflurane in dry soda lime containing KOH can undergo a Cannizzaro reaction to form methanol and formic acid, and ultimately produce formaldehyde, a respiratory irritant (Funk et al., 1999; Coppens et al., 2006). Fortunately, sevoflurane is stable in newer formulations of CO_2 absorbents that lack monovalent bases (Murray et al., 1999; Stabernack et al., 2000; Coppens et al., 2006).

Biotransformation

Like all fluorinated volatile anesthetics, sevoflurane is biotransformed to organic and inorganic fluoride metabolites (Kharasch, 1995). The in vitro rate of defluorination of sevoflurane is about the same as for methoxyflurane (Cook et al., 1975a, 1975b). In vivo, however, the serum F^- concentration associated with sevoflurane is much less than with methoxyflurane (Cook et al., 1975b; Holaday and Smith, 1981). Likely this difference is related to sevoflurane's reduced tissue solubility. Sevoflurane defluorination is increased by prior induction of microsomal enzymes with drugs such as phenobarbital (Cook et al., 1975a). Serum F^- concentrations from anesthetized horses are similar to those from humans under similar conditions (Aida et al., 1996; Driessen et al., 2002; Steffey et al., 2005a).

Central Nervous System

Like desflurane and other commonly used inhalation anesthetics, sevoflurane decreases cerebral vascular resistance and cerebral metabolic rate, and it increases intracranial pressure in a dose-related manner (Manohar and Parks, 1984b; Scheller et al., 1988, 1990). Sevoflurane's cerebral vasodilating potency is considered a little less than isoflurane and desflurane (Matta et al., 1999; Summors et al., 1999; Kaye et al., 2001; Holmstrom and Akeson, 2003). Compared with isoflurane or desflurane, sevoflurane can be associated with epileptogenic EEG activity in patients (Iijima et al., 2000; Voss et al., 2006), but sevoflurane is not commonly associated with gross motor evidence of seizure activity, at least in dogs (Wallin et al., 1975; Scheller et al., 1990).

Cardiovascular System

Sevoflurane's actions on the circulatory system are qualitatively and quantitatively similar to those of isoflurane (Manohar and Parks, 1984b; Bernard et al., 1990; Eger, 1994; Lerman et al., 1994; Ebert et al., 1995a, 1995b; Pypendop and Ilkiw, 2004). Sevoflurane does not increase the arrhythmogenicity of the heart (Wallin et al., 1975), and the arrhythmogenic dose of epinephrine in dogs anesthetized with sevoflurane is similar to that during isoflurane anesthesia (Hayashi et al., 1988).

Respiratory System

Sevoflurane does not elicit as much airway irritation, coughing, or breath holding as other halogenated ether anesthetics in people, and so is the potent volatile agent most commonly selected for inhaled anesthetic induction (Doi and Ikeda, 1993; TerRiet et al., 2000). However, differences between agents in the quality of anesthetic induction – aside from speed – are less apparent in domestic animals.

In humans, sevoflurane produces less respiratory depression than other modern halogenated ethers at light anesthetic planes, with arterial $P\text{CO}_2$ in spontaneously ventilating patients approximating values observed during equipotent doses of halothane anesthesia. However, respiratory depression at 1.4 times MAC, representing a moderate-to-deep anesthetic plane, is greater with sevoflurane than halothane (Doi and Ikeda, 1987b; Green, 1995).

In horses, sevoflurane tends to depress ventilation more than either isoflurane or halothane, even at light-to-moderate anesthetic planes (Grosenbaugh and Muir, 1998; Brosnan et al., 2012). More potent respiratory depression can delay anesthetic washout (Brosnan et al., 2012), resulting in similar recovery times in horses recovering from isoflurane or sevoflurane, despite the latter's much lower blood–gas partition coefficient (Soares et al., 2012).

Halothane

Halothane USP (Fluothane), is a polyhalogenated alkane first introduced into clinical practice in 1957 (Brennan et al., 1957). It is a racemic mixture of 2-bromo-2-chloro-1, 1, 1-trifluoro-ethane.

Advantages

At most clinically relevant equipotent doses, respiratory rate and ventilation are better maintained with halothane during spontaneous breathing compared with any of the modern halogenated ether-type anesthetics. In otherwise unmedicated healthy dogs and horses, the alveolar halothane concentration that is associated with complete respiratory arrest is 2.9 MAC (Regan and Eger, 1967) and 2.6 MAC (Steffey et al., 1977), respectively. Halothane also does not cause airway irritation; however, sevoflurane shares this property and consequently has replaced halothane use as an inhalation induction agent (Doi and Ikeda, 1993).

Disadvantages

Following are some undesirable features of halothane, many of which have contributed to its declining use and availability:

- Pharmacokinetics: Halothane has a much greater blood : gas partition coefficient than modern haloethers; hence, recovery from anesthesia is prolonged (Whitehair et al., 1993; Polis et al., 2001).
- Stability: Halothane requires a thymol preservative that can accumulate in vaporizers (Rosenberg and Alila, 1984).
- Biotransformation: As much as 40% of halothane undergoes liver metabolism, resulting in production of trifluoroacetic acid (Van Dyke and Wood, 1975). Other metabolites resulting from oxidative metabolism via the cytochrome P450 pathway are inorganic chloride (Cl^-) and to a lesser extent bromine (Br^-). In humans, Br^- from halothane breakdown will induce headache, ataxia, lethargy, and EEG alterations (Tinker et al., 1976).
- Cardiovascular: Halothane decreases myocardial contractility, cardiac output, and blood pressure more than equipotent doses of modern haloethers (Steffey et al., 1974b, 1974c; Merin et al., 1977; Steffey and Howland, 1980; Ingwersen et al., 1988; Grandy et al., 1989; Pagel et al., 1991a). It also predisposes the heart to premature ventricular extrasystoles in the presence of exogenous or endogenous catecholamines (Purchase, 1966; Joas and Stevens, 1971; Munson and Tucker, 1975; Johnston et al., 1976).
- Hepatic: Halothane decreases hepatic blood flow more than ether anesthetics and is commonly associated with an increase associated with an increase in hepatocellular leak enzymes, although patients are not typically symptomatic for hepatic injury (Gopinath et al., 1970; Gopinath and Ford, 1976; Ross and Daggy, 1981; Harper et al., 1982a, 1982b; Shingu et al., 1982a, 1982b; Engelking et al., 1984; Steffey et al., 1993). Infrequently, the metabolite trifluoroacetic acid can

form trifluoroacetylated protein adducts in hepatocytes and stimulate a severe, and often fatal, immune reaction known as “halothane hepatitis” (Satoh et al., 1985; Hubbard et al., 1988; Kharasch et al., 1996; Njoku et al., 1997). Similar hapten immune reactions are possible, but much rarer, with the modern ether agents (Lewis et al., 1983; Carrigan and Straughen, 1987; Martin et al., 1995; Njoku et al., 1997).

Methoxyflurane

Methoxyflurane, USP (Metofane, Penthrane), is a polyhalogenated methyl ethyl ether that was first synthesized in 1958 and introduced clinically a few years later (Artusio et al., 1960; Mazze, 2006). Methoxyflurane is 2, 2-dichloro-1, 1-difluoro-1-methoxy-ethane which lacks a chiral center.

Advantages

Modern haloethers can cause hyperalgesia at low concentrations. In contrast, methoxyflurane is analgesic even at subanesthetic doses (Romagnoli and Korman, 1962; Torda, 1963).

Disadvantages

Following are some of the undesirable effects of methoxyflurane:

- Pharmacokinetics: Methoxyflurane has a very high blood : gas partition coefficient (Soares et al., 2012), resulting in a very slow onset of general anesthesia and very prolonged recoveries (Stoelting and Eger, 1969a).
- Biotransformation: As much as 70–80% of body methoxyflurane is metabolized, a process that can continue for many days after recovery due to the high tissue solubility of the agent (Holaday et al., 1970; Mazze and Cousins, 1974; Yoshimura et al., 1976). Metabolites include fluoride ion, dichloroacetic acid, and methoxyfluoroacetic acid.
- Renal: Methoxyflurane metabolites can cause vasopressin-resistant polyuric renal failure (Crandell et al., 1966; Mazze et al., 1971; Mazze, 2006).

Enflurane

Enflurane USP (Ethrane, Compound 347), was synthesized in 1963, introduced for clinical trial in human patients in 1963, and released for general clinical human use in 1972 (Dobkin et al., 1968). A structural isomer of isoflurane (Figure 11.1), enflurane is a racemic mixture of 2-chloro-1-(difluoromethoxy)-1, 1, 2-trifluoro-ethane.

Disadvantages

Following are some undesirable features of enflurane:

- Pharmacokinetics: The enflurane blood : gas partition coefficient is greater than isoflurane, resulting in less desirable kinetics (Eger and Eger, 1985; Carpenter et al., 1986b).
- Central nervous system: Enflurane causes epileptiform activity on the electroencephalogram at moderate levels of anesthesia and can cause seizures (Joas et al., 1971; Neigh et al., 1971; Julien and Kavan, 1972; Clark and Rosner, 1973; Klide, 1976; Steffey et al., 1977; Steffey and Howland, 1978a; Bassell et al., 1982).

The Gaseous Anesthetic: Nitrous Oxide

Nitrous oxide USP (N_2O), is a colorless, nonirritant, slightly sweet-smelling, nonflammable gas. Nitrous oxide is commercially available as a gas stored in steel cylinders at a pressure of about 750 psi or nearly 50 atmospheres. It has many desirable properties, including low blood solubility (Table 11.3), limited cardiovascular and respiratory system depression, and minimal toxicity (Eger, 1985). A combination of rapid kinetics and high inspired fractions (due to low potency) allow anesthetists to take advantage of a “concentration effect” and “second gas effect,” but also may create tympany of gas filled spaces and “diffusion hypoxia” during recovery. The reader is referred elsewhere for more information on these topics (Eger, 1974, 1985).

Biotransformation

Nitrous oxide is metabolized (reductive pathway) by intestinal anaerobic bacteria to molecular nitrogen (N_2) and free radicals (Hong et al., 1980; Linde and Avram, 1980). Unlike other inhalation anesthetics, N_2O is not directly metabolized by animal tissues.

Central Nervous System

Nitrous oxide is not a potent anesthetic (Table 11.7) and under ambient conditions will not anesthetize a fit, healthy individual. Consequently, to get important benefits of N_2O it is necessary to use it in high inspired concentrations but at the same time remembering that as the concentration of N_2O is increased there is a change in the proportion and partial pressure of the various other constituents of the inspired breath, notably O_2. Consequently, to avoid hypoxemia, 75% of the inspired breath is the highest concentration that can be safely administered (at sea level to healthy individuals, less at altitude or in the face of, especially, cardiopulmonary disease). The potency of N_2O in animals important to clinical veterinary medicine is only about one-half the anesthetic potency of that found for humans. Thus, the value of N_2O in veterinary clinical practice is further compromised. When used, it serves as an anesthetic adjuvant; that is, it is used in conjunction with an injectable and/or another inhalation anesthetic. Since its depression of other vital organs such as the heart, lungs, kidneys, etc., is small in comparison, its purpose in this case is to reduce the amount of the primary, more potent inhaled or injectable anesthetic drug for anesthesia and thereby lessen overall harmful effects on vital organ function.

The effects of N_2O on the EEG are similar to those produced by the volatile anesthetics. At low subanesthetic levels (about 30%, inspired), N_2O increases EEG frequency and lowers voltage, and at higher subanesthetic concentrations (e.g., 60%), N_2O increases voltage. Adding N_2O to a light level of anesthesia produced by other drugs tends to increase voltage and decrease frequency (Eger, 1985).

N_2O causes an increase in cerebral blood flow, cerebral metabolic rate, and intracranial pressure. The magnitude of change seems to depend upon whether it is administered alone or in conjunction with other anesthetics. Dramatic increases in intracranial pressure occur in animals when N_2O is used alone (Theye and Michenfelder, 1968; Sakabe et al., 1978; Pelligrino et al., 1984), but these effects may be masked by coadministration of other potent volatile anesthetics at 0.5–1.0 MAC or greater (Reasoner et al., 1990; Roald et al., 1991; Cho et al., 1996). Nitrous oxide can be neuroprotectant under conditions of glutamatergic excitotoxcity and ischemia, but it might also directly cause neuronal vacuolization and cytotoxicity (Jevtovic-Todorovic et al., 1998, 2003a; David et al., 2003; Jevtovic-Todorovic and Carter, 2005).

Nitrous oxide is an analgesic. It stimulates α-adrenergic receptors in the locus ceruleus and opioidergic receptors in the periaqueductal grey (Zuniga et al., 1987; Fang et al., 1997a; Zhang et al., 1999; Sawamura et al., 2000), resulting in loss of inhibition of descending antinociceptive pathways (Sanders et al., 2008a). As an anesthetic adjuvant, N_2O use is associated with a blunting of autonomic responses that otherwise accompany painful surgical stimuli.

Cardiovascular and Respiratory Systems

Under ambient conditions the effects of N_2O on the cardiovascular and respiratory function (other than reducing the inspired O_2 concentration) are small compared to those of the other inhalation anesthetics. Nitrous oxide is a direct myocardial depressant. However, it also causes sympathetic nervous system stimulation, release of catecholamines, and an increase in systemic vascular resistance. The net result is minimal or no effect on systemic blood pressure in most species, and improved arterial pressures in cats (Eisele and Smith, 1972; Steffey et al., 1974a, 1974c, 1975; Steffey and Howland, 1978b; Eisele, 1985; Pypendop et al., 2003).

In some circumstances N_2O may contribute to an increased incidence of cardiac arrhythmias (Liu et al., 1982; Lampe et al., 1990a). There is some evidence to suggest that its use could contribute to an increased incidence of myocardial ischemia, possibly in circumstances where increased sympathetic tone is contraindicated (Philbin et al., 1985; Leone et al., 1988; Nathan, 1988, 1991; Diedericks et al., 1993).

Liver and Kidney

Nitrous oxide has little or no effect on liver or kidney function in patients exposed under most clinical circumstances (Eger, 1985; Lampe et al., 1990b, 1990c). Nitrous oxide interferes with several vitamin B_{12}-dependent reactions. The result is an irreversible inactivation of the enzyme methionine synthase that in turn results in a reduced amount of thymidine, an essential DNA base. The subsequent interference with DNA synthesis prevents production of both leukocytes and red blood cells by bone marrow. Similarly, exposure to N_2O can produce a polyneuropathy ("nitrous oxide neuropathy") that is indistinguishable from that associated with pernicious anemia, that is, subacute degeneration of the spinal cord (Deacon et al., 1980; Eger, 1985; Koblin et al., 1990). The bone marrow changes would be expected to be seen only in the sickest of patients and after about 10 hours or more of N_2O anesthesia (O'Sullivan et al., 1981). The neurological disease is most commonly associated with rare, long-term exposure in a grossly contaminated work environment or with chronic abuse of N_2O (a potential consideration in the management of the veterinary practice) (Layzer, 1978; Layzer et al., 1978; Eger, 1985; Weir et al., 1988).

Trace Concentrations of Inhalation Anesthetics: Occupational Exposure

In 1968, a published 20-year retrospective study (Bruce et al., 1968) suggested that anesthesiologists exhibited a trend toward higher incidences of death from reticuloendothelial and lymphoid malignancies. The possibility that waste inhalation anesthetics could be mutagenic, carcinogenic, and/or teratogenic raised considerable concern. Although chronic exposure to high concentrations of modern inhalants might be genotoxic or reduce fertility (Rowland et al., 1992; Wiesner et al., 2001), evidence from both animal and human studies strongly suggest that there are no significant health risks posed by chronic exposure to low concentrations of waste gases for most individuals (Burm, 2003). Regardless, it remains prudent to minimize unnecessary workplace exposure to all inhaled anesthetics. Additional information on scavenging and trace gas monitoring is available elsewhere (Dorsch and Dorsch, 2007; Tranquilli et al., 2007; Miller et al., 2014).

Injectable Anesthetic Agents

Lysa P. Posner

Injectable anesthetics provide a rapid means of producing sedation or anesthesia in veterinary patients. The four stages of anesthesia used to define central nervous system (CNS) depression are similar in a patient regardless of whether the anesthetic is injected or administered by inhalation. An advantage of injectable anesthetics, particularly when administered intravenously (IV), is the ability to proceed more rapidly through or bypass stage II anesthesia (the excitement stage). This allows for a rapid and smooth induction of anesthesia, which is aesthetically more pleasant for small animals and safer for personnel in large animals.

There is no anesthetic agent that produces ideal anesthesia under all circumstances. When evaluating an injectable anesthetic agent, it is important to evaluate both the pharmacokinetics (absorption, distribution, metabolism, and excretion) and the pharmacodynamics (the behavioral and physiological effects) of a particular drug in order to select an agent most suited to a particular clinical condition, in a particular species.

Indications for Injectable Anesthesia

Intravenous anesthetics produce rapid unconsciousness which is advantageous for the following reasons. Rapid induction of anesthesia allows for prompt intubation and control of the airway. Intubation can prevent aspiration, facilitates assisted ventilation, and the administration of oxygen, with or without an inhalant anesthetic. Injectable anesthetics allow for unobstructed visualization of the upper airway for examination or surgical procedures and well as endoscopic access to the upper and lower airways. Some IV anesthetics are anticonvulsant and can provide rapid control and reduction in CNS activity in seizing patients. Induction of anesthesia with injectable anesthetics is less stressful for most patients compared with an inhalant induction and attenuates the excitement seen during stage II anesthesia. For large animals (e.g., horses), preventing the excitement stage is paramount for patient and medical personnel safety. Total intravenous anesthesia (TIVA) techniques are increasing in popularity because they can decrease the stress response, are associated with better recoveries, provide cardiovascular stability, and maintain cerebral autoregulation better than inhalants, without the need for expensive anesthetic equipment. This is a particularly attractive method when anesthetizing animals in the field.

Intramuscular (IM) injection of anesthetics can be advantageous for fractious animals or for wildlife or exotic animals, where injectable agents can be administered remotely (e.g., dart or syringe pole).

Finally, injectable anesthesia decreases the exposure of people and the environment to inhalant gases.

Disadvantages of Injectable Anesthesia

In general, injectable anesthetic agents have a large volume of distribution and wake-up is associated with redistribution and then metabolism of the drug. Thus, it can be hard to fine-tune anesthetic depth and wake-up compared with the inhalant drugs that are generally excreted unchanged through the lungs quite rapidly. However, some of the currently available intravenous agents (e.g., propofol) have such short durations of action that depth of anesthesia can be readily adjusted by changing the administration rate. These types of drugs have made it possible for safe and satisfactory anesthesia without the use of inhalation agents.

Another potential disadvantage of injectable anesthetics is the potential for human abuse. Therefore, many injectable anesthetic agents, as well as agents commonly used concurrently with them, are classified as controlled substances under the 1970 US Controlled Substances Act. This places restrictions on purchase, storage, record keeping, and use of these drugs. (Proper handling of Controlled Substances is discussed in Chapter 56 of this book).

Properties of an Ideal Injectable Anesthetic Drug

There is no ideal injectable (or inhalation) anesthetic drug available at this time. One can, however, hypothesize what properties such a drug would have. These can be divided into physiological and pharmacological properties.

Ideal Physiological Properties

The ideal injectable anesthetic agent should produce unconsciousness and amnesia, as well as provide analgesia and muscle relaxation. The ideal drug would produce those qualities while maintaining physiological homeostasis; that is, there should be no adverse changes in cardiovascular, respiratory, gastrointestinal, CNS, or endocrine functions.

Ideal Pharmacological Properties

An ideal injectable anesthetic should have a wide margin of safety (high therapeutic index) in a variety of species. It should have a short duration of action and be noncumulative. The drug should be readily excreted unchanged, ideally by more than one route. A specific and complete reversal agent should be available. The ideal drug would be chemically stable, have a long shelf life, have a physiological pH, have a nontoxic vehicle, and would be inexpensive.

Barbiturate Anesthetics

History

Barbituric acid was first synthesized in 1864 by Adolph von Baeyer, but the compound was considered clinically useless (Short, 1983). In the early 1900s, the barbiturates or drugs derived from barbituric acid were shown to produce sleep and prevent seizures, and an anesthetic revolution took place. Barbiturates are CNS depressants and can be used at increasing doses to produce sedation, hypnosis, anesthesia, coma, and even death (euthanasia solutions). The major uses for barbiturates in veterinary medicine are as induction agents for anesthesia, anticonvulsants, and euthanasia agents.

Although short-acting barbiturates are still commonly used for anesthesia in both veterinary and human medicine worldwide, they are no longer available in the USA. The European distributors of barbiturate anesthetics will no longer sell them to the USA due to objections regarding their use in human executions (NPR, 2014). Barbiturates for use as anticonvulsants and for veterinary euthanasia solutions are still available in the USA. Euthanasia solutions are discussed in Chapter 16.

Classification

Chemistry: Barbiturates are derivatives of barbituric acid, which is a combination of malonic acid and urea (Figure 12.1, barbituric acid). The addition of an alkyl or aryl group at position 5 of the barbituric acid ring imparts CNS depressant effects. Further modification of the molecule by substituting sulfur (thio) for oxygen (oxy), at position 2 of the barbiturate acid ring, increases the lipid solubility (thiobarbiturates vs. oxybarbiturates) (Figure 12.1, thiopental and methohexital). Lipid solubility can also be enhanced by increasing the number of side chains at position 5a and 5b of the barbituric acid ring (Figure 12.1, thiopental). Increasing lipid solubility results in a decreased duration of action (shorter acting), an increased metabolic degradation, and an increased hypnotic potency (Figure 12.1, methohexital). Longer side chains at position 5 increases anticonvulsant activity (Figure 12.1, phenobarbital, pentobarbital).

Barbiturates are often classified by either their duration of action (e.g., long, intermediate, short, or ultrashort) or by their chemical structure. The chemical structure (e.g., oxybarbiturates, thiobarbiturates) of barbiturates determine the time of onset and duration of action, which in turn determines their use (Table 12.1).

How supplied: Barbiturates are poorly soluble in water at physiological pH. However, through chemical manipulation, they can be made to form water-soluble salts when added to alkaline aqueous solutions. These salts hydrolyze in water to form highly alkaline solutions with a pH usually between 9 and 10. If the high pH is not maintained (for example if mixed with acidic solutions) precipitation can occur. Thus although barbiturates are chemically acids they are prepared as salts that are bases. The high alkalinity of the solution makes it caustic if given perivascularly (can cause sloughing of tissue) but makes the solution fairly bacteriostatic. Barbiturates are delivered as a racemic mixture with their L-isomers nearly twice as potent as their D-isomers.

Mechanism of Action

Barbiturates are γ-aminobutyric acid ($GABA_A$) receptor agonists which enhance inhibitory neurotransmission. They increase GABA binding (primary inhibitory neurotransmitter) by decreasing the rate of dissociation of GABA from its receptor. Activation of the GABA receptors increases transmembrane chloride conductance, resulting in hyperpolarization of the postsynaptic cell membrane, which causes inhibition of the postsynaptic neuron. Barbiturates also block glutamate

Barbituric acid

binding (main excitatory neurotransmitter) at AMPA receptors.

Barbiturates depress the reticular activating system (RAS), which controls arousal and inhibit the development or spread of epileptiform activity. The RAS system is particularly sensitive to barbiturates (Harvey, 1975) and animals are unable to be aroused or to maintain the wakeful state following administration.

Furthermore, at high doses, barbiturates can decrease transmission of nerve impulses at nicotinic acetylcholine receptors in the neuromuscular junction (Arias et al., 2006). These effects occur because barbiturates decrease the sensitivity of polysynaptic junctions to the depolarizing action of acetylcholine, which results in muscle weakness.

Table 12.1 Classification of barbiturates by type of barbiturate and common use

Drug	Oxygen/ sulfur at position 2	Duration of action	Common use
Phenobarbital	Oxybarbiturate	~12 h	Anticonvulsant
Pentobarbital	Oxybarbiturate	1–2 h	Anesthesia/ euthanasia
Thiopental	Thiobarbiturate	~20 min	Anesthesia
Thiamylal	Thiobarbiturate	~20 min	Anesthesia
Methohexital	Oxybarbiturate	~10–15 min	Anesthesia

Indications

Barbiturates are used in veterinary medicine for rapid induction of general anesthesia, as anticonvulsants, and for euthanasia (for use as anticonvulsants and euthanasia solutions see Chapters 16 and 17).

Specific Barbiturates (Box 12.1)

Thiopental sodium (pentothal sodium, previously used name thiopentone sodium)**:** Thiopental is the most commonly used barbiturate in veterinary medicine worldwide. It is an ultrashort-acting thiobarbiturate and differs from pentobarbital only at the number 2 carbon where a sulfur molecule has replaced the oxygen (Figure 12.1). The drug is prepared as a sterile powder and after reconstitution with an appropriate diluent is administered by the intravenous route. Thiopental sodium is chemically designated sodium 5-ethyl-5-(1-methylbutyl)-2-thiobarbiturate. The drug is a yellowish, hygroscopic powder, stabilized with anhydrous sodium carbonate as a buffer (60 mg/g of thiopental sodium). Thiopental is

Box 12.1 Regulatory information

US Controlled Drug Status
- Thiopental: Schedule III controlled drug
- Phenobarbital: Schedule IV controlled drug
- Pentobarbital: Schedule II controlled drug
- Methohexital: Schedule IV controlled drug

Withdrawal Information for Food Producing Animals
- Thiopental: Extra label use: At least 1 day for meat; 24 hours for milk
- Phenobarbital: no regulatory information available
- Pentobarbital: no regulatory information available

US FDA Veterinary-Approved Products
- Thiopental is approved by the FDA for use in dogs and cats, but no products are currently available in the US.
- Pentobarbital is approved by the FDA for use in dogs and cats
- Pentobarbital: pentobarbital sodium for injection, 64.8 mg/ml, Schering-Plough
- Phenobarbital: none
- Methohexital:none

Human-Approved Products
- Thiopental: Pentothal No longer available in the US
- Pentobarbital: Pentobarbital sodium (Nembutal Sodium), 50 mg/ml, Ovation Pharmacy
- Phenobarbital: Phenobarbital sodium for injection (Generic), 30, 60, and 130 mg/ml
- Methohexital: Methohexital sodium (Brevital), JHP Pharmaceuticals, 500 mg multidose vials.

dispensed as a powder buffered with sodium carbonate which is commonly reconstituted with sterile water or sterile saline. Once reconstituted, thiopental has a pH between 9 and 10, which is caustic if administered perivascularly. The high alkalinity of the solution results in thiopental having a long shelf life, but as the solution ages it becomes less potent (Thurmon et al., 1996). Although supplied in an alkaline pH, thiopental is a weak organic acid with a pK_a value of 7.6, and has a relatively low ionization (39%) at plasma pH (Brandon and Baggot, 1981). The nonionizing moiety is highly lipid soluble, which allows for it to quickly penetrate the blood–brain barrier and thus it is a rapidly acting anesthetic.

In general, the 2.5% solution is used with small animals and the 2.5% or 5% solution is used with larger animals. Thiopental can be mixed with propofol in a 1 : 1 (vol : vol) ratio, which is chemically stable (Paw et al., 1998). The combination of the two GABA agonists produces a synergistic clinical effect and improves the induction and recovery profile of thiopental to more resemble that of propofol (Ko et al., 1999).

Thiopental, like most barbiturates, undergoes extensive liver metabolism.

Thiamylal (Surital)**:** Thiamylal was an ultrashort-acting thiobarbiturate commonly used in veterinary medicine, but is no longer commercially available. Information on this drug can be found in earlier editions of this book.

Pentobarbital sodium (Nembutal sodium)**:** Pentobarbital is a short-acting oxybarbiturate that has been used in veterinary medicine since the early 1930s. Although commonly used in the past for clinical anesthesia, it current use is primarily as a euthanasia solution (see below in this section) and for anesthesia in laboratory rodents. Pentobarbital is effective when given intraperitoneally as well as intravenously and thus can be used successfully in small rodents. It undergoes extensive hepatic metabolism and is totally dependent on the liver for biotransformation and elimination. Animals can show excitement during induction and recovery, which can be prevented by concurrent use of tranquilizers or sedatives.

The duration of action of pentobarbital is much longer (four to eight times) than thiopental in most animals and therefore is therefore less commonly used for anesthesia. However, its long duration of action makes it clinically useful for anticonvulsant treatment.

Euthanasia solutions: Pentobarbital is the primary ingredient in most commercially available euthanasia solutions. See Chapter 16 for more detailed discussion of euthanasia solutions. Lidocaine and phenytoin are often added to increase cardiovascular depression as well as change the solution from a schedule II controlled drug to a schedule III controlled drug. The lethal dose of pentobarbital in the dog is 85 mg/kg orally and 40–60 mg/kg intravenously. Toxicosis, including death, has been reported in dogs fed uncooked meat from a horse euthanatized 8 days previously with pentobarbital (Polley and Weaver, 1977). Cooking does not inactivate pentobarbital in meat, as animals euthanatized with pentobarbital and rendered at a commercial plant showed virtually no degradation of the drug (O'Connor et al., 1985). The recommended dose for euthanasia is 87 mg/kg IV.

Phenobarbital sodium (Luminal, Phenobarbitone)**:** Phenobarbital was first synthesized in Germany in 1912 and was marketed as Luminal. It is a long-acting oxybarbiturate, whose current primary use is as an anticonvulsant or for long-term sedation (e.g., for treatment of animals with strychnine poisoning or tetanus). More information about the anticonvulsant use of phenobarbital is in Chapter 17.

Methohexital sodium (Brevital): Methohexital is a unique oxybarbiturate in that it is ultrashort acting. Methohexital is twice as potent as thiopental (Turner and Ilkiw, 1990) but has a higher incidence of CNS excitatory effects. Methohexital activates abnormal EEG tracings in epilepsy-prone subjects (Musella et al., 1971). Methohexital should not be used in patients with increased CNS excitation (e.g., strychnine poisoning) or with seizure disorders.

Methohexital should be administered intravenously; however, perivascular injection does not produce tissue irritation. Administration of methohexital should be fairly rapid since slow injection rates can be associated with muscular tremors and excitement. Excitement and muscle tremors can be reduced by prior administration of sedatives or tranquilizers.

The duration of action of methohexital is short, with dogs and cats attaining sternal recumbency within 5–10 minutes of administration (Sams et al., 1985). Although methohexital is metabolized four to five times faster than thiopental, awakening is due to redistribution rather than metabolism. In Greyhound dogs, recovery from methohexital anesthesia is significantly faster than from thiopental (Sams et al., 1985) and until the introduction of propofol to veterinary practice, methohexital was considered the induction agent of choice for Greyhound dogs.

Physiological Effects

CNS effects: Barbiturates are administered to produce anesthesia (short-acting barbiturates) or as anticonvulsants (long-acting barbiturates). However, they possess properties that are favorable to cerebral physiology. Barbiturates decrease cerebral blood flow (CBF) (Albrecht et al., 1977) and cause a dose-dependent depression of the electroencephalogram (EEG), eventually resulting in a flat EEG (Kiersey et al., 1951). They decrease cerebral oxygen consumption ($CMRo_2$) particularly in cortical areas by up to 55%, which parallels the depression of the neuronal activity. Metabolic needs of the brain remain constant; only hypothermia will decrease cerebral metabolic needs (Steen et al., 1983). Furthermore, they decrease intracranial pressure (Bedford et al., 1980) and similarly decrease intraocular pressure (Mirakhur and Shepherd, 1985). Since intracranial pressure (ICP) decreases more than mean arterial pressure (MAP), cerebral perfusion pressure is preserved. Thus barbiturates like thiopental are often chosen to anesthetize patients with CNS disease or trauma.

Methohexital, is an ultrashort-acting barbiturate, but is an exception to the cerebro-friendly status of barbiturates. Methohexital has been associated with generalized excitement and activation of epileptic foci (Stoelting, 1999) and is not recommended for patients with a seizure history.

Cardiovascular system: Barbiturates cause changes in the cardiovascular system that is dependent on the dose and the physiological status of the patients. In healthy dogs, there is a decrease in stroke volume and contractility with an increase in heart rate (Turner and Ilkiw, 1990). In the healthy dogs, there is a minimal change to cardiac output as the reflex tachycardia compensates for the decrease in stroke volume, but mild hypotension is often seen.

Although unproved, anecdotal reports suggest that in compromised dogs, barbiturates result in an exaggerated cardiovascular depression. However, healthy dogs that suffered from acute blood loss did not show a depression in cardiovascular parameters (Ilkiw et al., 1991a). Dogs and pigs do, however, need a smaller induction dose following severe hemorrhage (Weiskopf and Bogetz, 1985). Caution should be used when administering barbiturates to patients with dehydration, hypovolemia, anemia, blood loss, or underlying cardiac disease.

Thiopental can precipitate ventricular arrhythmias, particularly bigeminy (Muir, 1977), as well as potentiate epinephrine-induced arrhythmias (Atlee and Malkinson, 1982). Lidocaine can be administered with thiopental. This allows for less thiopental to be administered (reduces cardiovascular depression) and protects against ventricular arrhythmias (Rawlings and Kolata, 1983). Caution should be used when administering thiopental to patients with high sympathetic tone or who are prone to arrhythmias.

There is a dose-dependent effect of the vasomotor center by barbiturates. Rapid IV injection of an induction dose of a thiobarbiturate causes a sharp but transitory fall in arterial pressure because of the high concentration briefly depressing the vasomotor center. Venodilation results in splenic sequestration of red blood cells (RBC) and a concomitant drop in packed cell volume. For this reason barbiturates are often avoided for anesthesia of patients scheduled for a splenectomy (Baldo et al., 2012). Furthermore, the vasodilation contributes to heat loss. With a decline in heat production during anesthesia and an increase in heat loss owing to peripheral vasodilation, anesthetized patients can quickly become hypothermic.

Barbiturates do not block the autonomic responses to pain or intubation and thus should be administered with drugs that will attenuate those responses (e.g., opioids).

Respiratory effects: When used at anesthetic induction doses, barbiturates produce central respiratory depression. There is a decrease in respiratory rate and minute ventilation, with apnea in some patients (Quandt et al., 1998). In addition to causing respiratory depression, the barbiturates decrease the reflex responses to hypercapnia and hypoxemia (Hirshman et al., 1975). Following induction with a barbiturate, patients should be intubated and assisted with ventilation as necessary. The blood concentration inhibiting the respiratory center is considerably less than that arresting the heart, so patients that are apneic may be stable cardiovascularly. The occurrence of bigeminy appears to be decreased in well-oxygenated patients. Oral barbiturates used as anticonvulsants have minimal or no effect on respiratory function, probably due to lower plasma concentrations.

Muscular effects: Barbiturates produce good muscle relaxation and generally produce favorable intubating conditions. Laryngeal reflexes are preserved with barbiturate anesthesia (Jackson et al., 2004) facilitating better evaluation of laryngeal function. The increased sensitivity of laryngeal and bronchial reflexes can lead to laryngospasm (Barker et al., 1992). Although laryngeal reflexes are preserved, all patients induced with a barbiturate should be intubated to protect the airway and support ventilation.

Gastrointestinal (GI) tract: There are no important effects such as diarrhea or intestinal stasis following routine use of thiobarbiturates.

Kidney: The thiobarbiturates have no direct effect upon the kidney, but can decrease urine output because of decreased blood flow and glomerular filtration rate resulting from hypotension and decreased cardiac output. Patients with uremia have decreased plasma binding of barbiturates (more physiologically available drug) and thus need lower induction doses (Ghoneim and Pandya, 1975).

Fetus/neonates: Most barbiturates easily cross the placenta and equilibrium between maternal and fetal circulations is established within a few minutes. While in utero, most fetuses are slightly acidemic when compared to the mother. Since barbiturates are less ionized in an acid environment, it is possible that the neonate will have a greater concentration of active drug. In humans, anesthesia with thiopental for cesarean sections resulted in neonates with depressed reflexes, altered acid–base status, and delayed suckling when compared to epidural anesthesia (Sener et al., 2003). Similarly, neurological function was depressed in puppies following cesarean sections where the dam was administered thiopental (Luna et al., 2004). Pentobarbital has been associated with slow neonatal recovery, delayed nursing, and increased morbidity (Thurmon et al., 1996). Phenobarbital is excreted in the milk, although the amounts are marginal. However, a suckling neonate can ingest the drug passed from the mother (Wong et al., 2008). Because neonates may have impaired clearance compared to an adult, this can potentially lead to adverse effects (sedation and decreased suckling activity).

Miscellaneous: Doses of thiobarbiturates that produce surgical anesthesia depress basal metabolism so that less body heat is produced during anesthesia concurrently with excessive heat loss as a result of vasodilation. It is important that surgical patients anesthetized with barbiturates be kept warm.

The decrease in vasomotion associated with barbiturates also leads to splenic sequestration of RBCs. Since the spleen can become quite large and a significant amount of blood and be stored in the spleen, barbiturates are not recommended for patients having a splenectomy.

The “glucose effect” is a term used to describe a reanesthetizing action seen in animals recovering from barbiturate anesthesia that are administered glucose solutions. Glucose decreases microsomal metabolism and thus can decrease barbiturate metabolism (Peters and Strother, 1972). A similar event can occur with administration of epinephrine; however, little clinical effect is seen at routine barbiturate doses (Hatch, 1966).

Analgesia: Barbiturates do not provide analgesia. While anesthetized, nociceptive input is not perceived by the brain, but the pain pathways are activated. In patients where pain will continue following anesthesia, alternative analgesics must be used. At subanesthetic doses, barbiturates may cause hyperalgesia (Ewen et al., 1995), but this effect is controversial and probably not clinically relevant when barbiturates are used as induction agents.

Pharmacokinetics

Thiopental: Thiopental is highly protein bound (>70%) (Brandon and Baggot, 1981) and has a pKa near 7.6. After IV administration, thiobarbiturates are initially present in high concentrations in highly perfused tissues (e.g., the brain), resulting in rapid induction of general anesthesia. Thiobarbiturates then redistribute to the moderately perfused body tissues (e.g., muscle). This redistribution to moderately perfused tissues decreases the concentration in the plasma in brain tissues allowing the animal to regain consciousness. Further redistribution to adipose tissue from both highly and moderately perfused tissues results in the complete recovery from thiobarbiturate anesthesia. Animals with lower percentages of fat and/ or muscle tissue have a smaller percentage of area for the barbiturates to redistribute to. Thus normally lean patients (e.g., Sighthounds), neonates, or cachetic patients might have prolonged recoveries from thiobarbiturates. Similarly, since awakening depends of redistribution, repeated dosing is not recommended because of cumulative effects and prolongation of recovery.

Pharmacokinetics of thiopental in rabbits, sheep, and dogs showed an central volume of distribution of 38.6 ± 10 ml/kg, 44.5 ± 9.1 ml/kg, and 38.1 ± 18.4 ml/kg, respectively (Ilkiw et al., 1991b). Elimination half-life was longest in the sheep (251.9 ± 107.8 min), shorter in the dog (182.4 ± 57.9 min), and shortest in the rabbit (43.1 ± 3.4 min) (Ilkiw et al., 1991b).

The activity of a drug is dependent on the percentage of the drug that is unbound and unionized. Since thiopental is an acid it is nonionized in an acid environment. It is also highly protein bound. Many ill patients are both acidemic and hypoproteinemic and thus may have greater percentage of active drug available for pharmacological activity. Thus, the therapeutic index may be smaller in ill patients, making them easier to overdose.

Phenobarbital: Phenobarbital is readily absorbed from the GI tract with bioavailability ~90% in dogs (Pedersoli et al., 1987) and ~99% in horses (Ravis et al., 1987). Pharmacokinetics of an IV bolus dose of phenobarbital in horses showed a volume of distribution at steady state of 0.803 ± 0.07 l/kg; terminal phase elimination of 18.3 ± 3.65 hours; and total body clearance 30.8 ± 6.2 ml/kg/h (Duran et al., 1987). In the dog, volume of distribution is ~0.7 L/kg; the mean half-life was 92.6 ± 23.7 hours; mean total clearance 5.6 ± 2.31 ml/h/kg (Pedersoli et al., 1987). In the goat, the volume of distribution for pentobarbital (30 mg/kg) administered intravenously is 0.72 l/kg; the first-order disappearance rate kinetic constant is 0.76 hour and the half-life is 0.91 hour (Boulos et al., 1972).

Phenobarbital: In dogs, the elimination phase half-life of pentobarbital is 8.2 ± 2.2 hours. The steady-state volume of distribution is 1.08 ± 0.21 liters/kg and the elimination clearance is 0.0013 ± 0.0004 liters/min (Frederiksen et al., 1983). It is 35–45% protein bound. Comparatively, ruminants, especially sheep and goats, metabolized pentobarbital much faster; elimination half-life in goats is ~1 hour compared to ~8.0 hours in dogs.

Metabolism

Barbiturates are almost completely biotransformed in the liver and eliminated by the kidney. Most barbiturates are metabolized principally by the hepatic microsomal enzyme system and cause microsomal enzyme induction (CYP450 system). This can result in altered metabolism of other drugs as well of the barbiturate itself if given repeatedly. Neonates, cachetic, or hypothermic animals can have decreased microsomal metabolism and thus these drugs may have a prolonged effect in these animals. Recovery times for patients with hepatic dysfunction can be markedly prolonged, but fairly normal in patients with renal dysfunction.

Although awakening from thiobarbiturates is generally more rapid than from oxybarbiturates (except for methohexital), this is due to rapid redistribution rather than from rapid metabolism.

Greyhounds are deficient in oxidative enzymes needed for metabolism of thiobarbiturates (Robertson et al., 1992). Thus along with having low fat stores, metabolism is extremely prolonged and awakening may be >8 hours. Thiobarbiturates should not be used in Greyhounds.

Tolerance has been reported with multiple or frequent use of barbiturates. It can occur as a sequela to the induction of microsomal enzyme activity (i.e., increased metabolism) or as a general neurological adaptation to chronic barbiturate effects.

Adverse Effects/ Contraindications

Barbiturates can cause sequestration of RBC in the spleen from venodilation. Thus, these drugs are often avoided for a splenectomy. Thiobarbiturates should not be used in Greyhound dogs (see Section Metabolism). Perivascular administration of thiobarbiturates can result in tissue damage and necrosis (sloughing). Infiltration with saline and lidocaine has been recommended for treatment of perivascular injections (Tuohy and MacEvilly, 1982).

Dose

Table 12.2 shows dose ranges to produce anesthesia for common barbiturates in different species. Lower doses are generally used when patients are premedicated with other CNS depressant or have serious concurrent disease and higher doses are generally needed when no other drugs are given. The use of premedicants with barbiturate anesthesia produces a smoother induction and recovery.

The pH of thiopental is ~10 and therefore should only be given IV, as any injection outside of the vein can lead to pain, tissue injury, and skin sloughing. Intraarterially, barbiturates, in particular thiopental, produce spasm of the arterial wall, which can lead to thrombosis and poor perfusion if collateral circulation is not present (e.g., pinnae of ear, digits). Thiopental should not be administered into body cavities.

Thiopental should be administered "to effect." That is, the entire dose is calculated but given slowly until the desired effect is present; usually the end-point is a patient that can be easily intubated. The slower-acting barbiturates need to have a portion of the dose "bolused" to prevent seeing the excitement stage. If thiopental is given after premedication, this quick bolus is unnecessary.

Most barbiturates have a similar but small therapeutic index (lethal dose/ therapeutic dose); however, the shorter-acting barbiturates have fewer postanesthetic complications because of their shorter duration of action.

Increased risk with clinically ill patients: Since World War II, warnings have been issued about the increased mortality with the use of barbiturates in trauma patients

Table 12.2 Doses of common barbiturates in various species

	Thiopental (mg/kg IV)	Pentobarbital (mg/kg IV[a])	Phenobarbital (mg/kg IV)	Methohexital (mg/kg IV)
Dog	8–22	2–30	6.0	3–11
Cat	8–22	2–15	6.0	3–11
Horse	4–15		1.0–10.0	5
Cow	4–22			
Sheep	8–15	20–30		
Goats	8–20	20–30		
Llamas	6–15			
Pigs	5–12	10–30		5–8
Mice		30–90 (IP)		
Rats		20–40 (IP)		
Rabbits	20–50	15–40		10
Chickens	20			
Primates	2–20	37		2

[a] Dose of pentobarbital for euthanasia is 87 mg/kg.
IP, intraperitoneal.

(Halford, 1943). Trauma or critically ill patients are more likely to be acidemic and hypoproteinemic and thus will have an increased fraction of unionized (active) drug available. Uremia can also decrease protein binding and increase the percentage of active drugs. Dogs and pigs with acute blood loss need smaller induction doses (Weiskopf and Bogetz, 1985). Thus these patients are more easily overdosed and care should be used to assure appropriate dosing. However, with proper dose adjustments, the risks for barbiturate use with critically ill patients can be minimized and these drugs can be used safely (Bennetts, 1995).

Duration of action

Duration of action of thiopental in dogs is fairly short with extubation occurring 25.2 ± 15.7 min after an induction dose and ability to walk unaided at 72.8 ± 26.1 minutes (Quandt et al., 1998). Since all of the barbiturates require extensive liver metabolism, it should be expected that neonates and animals with hepatic dysfunction would have a prolonged duration of action. There is also significant individual variation based on sex, weight, nutritional status, body temperature, and breed as well as the type of barbiturate used. For example, thiobarbiturates have a longer duration in Greyhound dogs than in mixed breeds (Robertson et al., 1992). Alternatively, methohexital, an oxybarbiturate, induces a shorter period of anesthesia in the Greyhound dogs than thiopental, a thiobarbiturate (Robertson et al., 1992). Various reasons have been given for the differences in Greyhound dogs as compared to other breeds (Robinson et al., 1986; Court, 1999).

Chloramphenicol can double the duration of action of pentobarbital because it inhibits the microsomal enzymes responsible for metabolism of some barbiturates. Since awakening from thiobarbiturates is primarily due to redistribution rather than metabolism, the concurrent administration of chloramphenicol with thiopental does not prolong awakening when both drugs are used at clinically relevant doses (Reich et al., 2005).

Species Differences

Dogs - sighthounds: Since awakening from anesthesia is due to redistribution of barbiturates to fat and muscle, lean breeds with small fat stores (e.g., Whippet, Irish Wolfhounds) can show a prolonged effect to barbiturates. With little area to redistribute the drug, these breeds also have an increased risk of overdose.

Dogs – Greyhounds: Greyhounds are classified as Sighthounds and are at risks as discussed above. In addition, Greyhounds are deficient in oxidative enzymes needed for metabolism of thiobarbiturates and thus can have extremely prolonged recoveries (Robinson et al., 1986). Although not toxic, the increased risk of overdose coupled with the prolonged recovery makes thiopental not recommended for use Greyhounds.

In Greyhounds, recovery from methohexital anesthesia is significantly faster than from thiopental (Sams et al., 1985). Currently, propofol is more commonly used in Greyhounds for anesthesia than barbiturates.

Ruminants: Barbiturates can be successfully used for anesthesia in ruminants, but because of the propensity for ruminants to regurgitate, the airway needs to be protected by placement of a cuffed orotracheal tube.

In cattle, a congenital condition ("pink tooth") that increases porphyrin concentrations can occur, which can lead to neurological disturbances from demyelination of peripheral and cranial nerves. In the liver, barbiturates stimulate production of an enzyme that increases porphyrin production potentially making the disease worse (Mees and Frederickson, 1975). Animals afflicted with a known or suspected disturbance in porphyrin metabolism should not be administered barbiturates.

Swine: Many pigs may have prolonged recoveries from thiopental administration (~1 hour) versus other animals (~15 minutes). It is possible that redistribution of thiopental to the increased fat stores may contribute to the prolonged effect of the drug. Barbiturates do not trigger malignant hyperthermia.

Horses: The administration of thiopental to horses without prior sedation is not recommended as there is significant excitement and incoordination. Rather, horses should be administered thiopental following sedation with an α_2-agonist (e.g., xylazine) and/or guaifenesin, and/or a benzodiazepine (e.g., diazepam). Induction of anesthesia with thiopental causes horses to become recumbent by the flexion of all four legs, as compared to ketamine where most horses will flex their hind legs first and assume a dog-sitting posture before complete recumbency. Care should be taken to prevent horses from injuring themselves during induction and recovery. Methohexital should not be used alone in horse because excitation during induction and/ or recovery.

Birds: Thiopental has been successfully used in birds interosseously (Valverde et al., 1993), but because of prolonged recoveries and increased mortality it is not recommended.

Reptiles: Barbiturates are metabolized very slowly in reptiles resulting in a prolonged recovery. The ultrashort-acting barbiturate, methohexital, has been used with varying duration of action in snakes (Preston et al., 2010).

Drug Interactions

All CNS depressants (e.g., opioids, α_2-agonists, phenothiazine sedatives) can potentiate the effects of barbiturates, reducing the required induction dose and increasing the risks of physiological side effects. Long-acting barbiturates induce hepatic microsomal enzymes, which increases the metabolism of other drugs metabolized by the same system (e.g., chloramphenicol, beta-blockers, and metronidazole). The induction of microsomal enzymes does not occur after a single dose. Therefore, the likelihood of this occurrence is low with anesthetic uses. However, it is common when repeated oral doses are administered such as when phenobarbital is administered as an anticonvulsant in animals.

The other important interaction that can occur is through microsomal enzyme inhibition. (Anticonvulsant drugs are covered in more detail in Chapter 17.) As discussed in Section Metabolism, drugs known to be CYP450 inhibitors, such as chloramphenicol, can inhibit the metabolism of barbiturates and prolong recovery.

Overdosage/Acute Toxicity

Treatment for an overdose with short-acting barbiturates should center on supportive treatment of respiratory and cardiovascular depression. This may include positive pressure ventilation, fluid therapy, and inotropic support. Clearance of long-acting barbiturates is considerably greater in alkaline than in acid urine. This occurs because alkaline urine produces ionization of the drug and prevents tubular reabsorption. Thus alkalinization of urine with sodium bicarbonate increases the elimination rate and is clinically useful in treatment of intoxication from long-acting barbiturates.

If a known perivascular injection occurs, the area should be infiltrated with saline for dilution and acidification and a local anesthetic to decrease pain.

Propofol

History

Propofol is an intravenous anesthetic used for sedation, induction of anesthesia, or maintenance of anesthesia when administered as a constant rate infusion (CRI). It has been approved for human use since 1989 and is popular in veterinary medicine due to its smooth induction and recovery. It is unusual in that it is supplied in a milky white emulsion that is administered intravenously.

Classification

Chemistry: Propofol (2,6-diisopropylphenol) (Figure 12.2) is an alkyl phenol derivative that is water insoluble but highly lipid soluble. Propofol is chemically described as 2,6-diisopropylphenol and has a molecular weight of 178.27. Propofol is very slightly soluble in water and is therefore formulated as a white, oil-in-water emulsion.

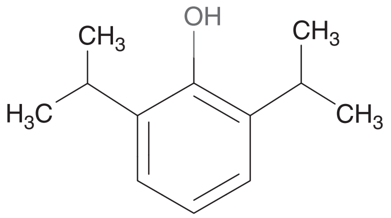

Figure 12.2 Structure of propofol.

How supplied: There are a number different propofol formulations marketed to the human and veterinary markets. Most of the formulations are similar; however, some contain small amounts of EDTA or benzyl alcohol. PropoFlo^{TM} Injection is a sterile, nonpyrogenic emulsion containing 10 mg/ml of propofol suitable for intravenous administration. In addition to the active component, propofol, the formulation also contains soybean oil (100 mg/ml), glycerol (22.5 mg/ml), egg lecithin (12 mg/ml), and oleic acid (0.6 mg/ml) with sodium hydroxide to adjust the pH. The propofol emulsion is isotonic and has a pH of 6.0–9.0. The formulation available contains no preservatives and will support bacterial growth (Wachowski, 1999). Since propofol is an emulsion it should be shaken well before using.

Propofol with extended shelf life, PropoFlo^{TM} 28, is a sterile, nonpyrogenic emulsion containing 10 mg/ml of propofol in a multidose vial for intravenous administration. The name "PropoFlo 28" is used because, compared to previous formulations, it has a 28-day shelf-life once the vial is opened. This is designed to reduce anesthetic waste and no refrigeration is required for the 20-ml and 50-ml vial sizes. Each ml contains 10 mg propofol. The PropoFlo^{TM} 28 emulsion is isotonic and has a pH of 6.0–8.5. PropoFlo 28 is approved for use in dogs, only. The effects of the benzyl alcohol preservative in cats have not been studied and therefore cannot be recommended.

Propoclear® was a propofol formulation that did not use a lipid carrier. The solution was clear and pharmacodynamic effects were similar to standard formulations of propofol. However, the product was associated with increased injection site reactions and was removed from the market (Hill and Williams, 2011).

Mechanism of Action

Propofol produces CNS depression by its effect on the $GABA_A$ receptor (Ying and Goldstein, 2005). Propofol decreases the rate of GABA dissociation from its receptors thus increasing the opening of chloride channels. Increased calcium conductance results in hyperpolarization of postsynaptic cell membranes and inhibition of the postsynaptic neurons resulting in anesthesia and amnesia.

Although shown to be anticonvulsant in veterinary and human patients with variable CNS disease (Brown and Levin, 1998; Steffen and Grasmueck, 2000), the mechanism of action as an anticonvulsant is unknown.

Indications

Clinical uses of propofol include: induction of general anesthesia, short-term sedation, long-term sedation (e.g., ventilator patients), maintenance of anesthesia (via constant rate infusion), and treatment of status epilepticus. Propofol should only be administered intravenously; however, extravasation does not cause skin sloughing as it does with barbiturate anesthetics.

Physiological Effects

CNS effects: Propofol induces CNS depression by enhancing the effects of GABA, an inhibitory neurotransmitter, providing a rapid, smooth induction of general anesthesia.

Propofol produces a favorable neurological status as it decreases ICP, decreases cerebral perfusion pressure, and decreases cerebral metabolic oxygen consumption (Pinaud et al., 1990). Since cerebral metabolic demands are decreased more than blood flow decreases, perfusion is adequate. Intracranial pressure is reduced in patients with both normal and elevated ICP. Propofol has also been shown to maintain cerebral autoregulation in pigs (Lagerkranser et al., 1997) and increase cerebral autoregulation in humans (Harrison et al., 2002).

Similar to its effects on intracranial pressure, propofol causes an acute decrease in intraocular pressure by 30–40% when administered at anesthetic doses (Neel et al., 1995).

Myoclonus has been reported following propofol administration and some have hypothesized that propofol might lower the seizure threshold. However, propofol has been shown to be anticonvulsant and does not produce seizure activity in patients with documented epilepsy (Cheng et al., 1996). Propofol has been used successfully in both dogs and humans for long-term control of status epilepticus (Brown and Levin, 1998).

Following propofol anesthesia, many human patients report a feeling of euphoria as well as having had amorous dreams (Canaday, 1993). Many domestic animals recover from propofol clear headed, coordinated, and seemingly feeling well.

The combination of good CNS perfusion, good quality recovery in patients with CNS disease (Caines et al., 2014), and anticonvulsant properties, makes propofol is a popular anesthetic for patients with CNS disease.

Cardiovascular effects: Induction doses of propofol are associated with systemic hypotension (Reich et al., 2005). Although propofol causes negative inotropy, the decrease in blood pressure is primarily via a decrease in systemic vascular resistance (vasodilation); systemic vascular resistance decreased by 21% in dogs following an induction dose of propofol (5 mg/ml) (Wouters et al., 1995). The decrease in system vascular resistance likely contributes to splenic engorgement and this should be considered in patients anesthetized for splenectomy (Baldo et al., 2012). Following an induction dose of propofol, the heart rate is often decreased or unchanged, even with systemic hypotension (Whitwam et al., 2000). This is contrast to the barbiturates where there is often an increased heart rate in response to the decrease in blood pressure. Therefore a decrease in cardiac output should be expected.

Propofol can enhance the ability of epinephrine to induce cardiac arrhythmias but does not appear to be inherently arrhythmogenic (Kamibayashi et al., 1991).

Respiratory: Apnea is a commonly seen following bolus administration of propofol. The apnea associated with propofol is increased as the rate of infusion is increased. That is, the faster the administration the more likely the incidence of apnea (Musk et al., 2005). Respiratory depression resulting in mild hypercapnia and acidosis are also seen in spontaneously breathing dogs following induction doses (Robertson et al., 1992) and in dogs administered propofol as a constant rate infusion. Patients given propofol should be monitored for hypoxemia and hypercapnia and if necessary the patient should be intubated and provided supplemental oxygen. Propofol should be cautiously in patients where securing an airway may be difficult (e.g., laryngeal masses, guinea pigs, etc.).

Muscular effects: Propofol provides excellent muscle relaxation, but occasionally results in short and long-term myoclonic movements in humans and dogs (Nimmaanrat, 2005). Signs resolve spontaneously, but severity of movement can interfere with surgical procedures. Anecdotal treatment with ketamine at 1 mg/kg IV has resulted in the resolution of signs, whereas treating with benzodiazepines does not appear to affect the myoclonus (author's personal experience). Laryngeal reflexes are decreased and result in a favorable intubating environment, but might increase the risk of aspiration in patients without a protected airway.

Miscellaneous: Propofol crosses the placenta and enter the fetal circulation, but it appears to be readily removed from the fetal circulation after birth and produces minimal effects on healthy, newborn, human infants (Dailland et al., 1989) or puppies (Luna et al., 2004).

Propofol does not cause histamine release (Mitsuhata and Shimizu, 1993) and results in a diminished stress response compared with inhalant anesthetics (Ledowski et al., 2005).

Propofol has antioxidant effects in humans, dogs, and pigs (Aldemir et al., 2001; Allaouchiche et al., 2001; Lee, 2012). The clinical relevance of this activity is unclear.

Propofol has been shown to decrease postanesthetic nausea and vomiting in people at both anesthetic and subanesthetic doses (Apfel et al., 2004); however, this effect has not been documented in domestic animals.

Subanesthetic IV doses of propofol have been shown to decrease the pruritus seen following spinally administered opioids in humans (Horta et al., 2006).

Propofol does not provide any analgesia or produce hyperalgesia as has been reported with barbiturate anesthesia (Wilder-Smith et al., 1995).

Pharmacokinetics

The pharmacokinetics of propofol in dogs was described using a two-compartment open model (Zoran et al., 1993). Initially, the drug is extensively taken up by the CNS, resulting in rapid CNS depression and induction of anesthesia. It is then rapidly redistributed from the brain to other tissues and removed from the plasma by metabolism. Propofol's lipophilic nature results in a large apparent volume of distribution (Vd; 17.9 l/kg in mixed-breed dogs) and steady-state volume of distribution ($\mathrm{Vd}_{\mathrm{ss}}$ 9.7 ml/kg). The initial distribution half-life ($t_{1/2\alpha}$) is short, as is the plasma disappearance ($t_{1/2\beta}$), due to rapid redistribution of the drug from the brain to other tissues and extensive metabolism. The Vd and $\mathrm{Vd}_{\mathrm{ss}}$ are smaller in Greyhounds, 11.2 l/kg and 6.3 ml/kg respectively, which will produce higher concentrations at similar doses compared to other breeds, and there may be slower recoveries compared with other dogs (Zoran et al., 1993). Geriatric dogs (>8.5 years) have also been shown to have a slower clearance than that reported for younger dogs (Reid and Nolan, 1996). Slower systemic clearance may also account for the prolonged effects in Greyhounds and geriatric dogs (see Section Metabolism).

The pharmacokinetics of propofol in cats has not been fully determined; however, cats appear to have a similar response to and dose requirement as dogs for propofol. Interestingly, it has been shown that in cats there is a significant pulmonary uptake of propofol (Matot et al., 1993).

Propofol does not accumulate (noncumulative) after repeated doses and/or prolonged infusions in dogs or laboratory animals (Adam et al., 1980; Mandsager et al., 1995); however, in cats longer constant rate infusions resulted in a longer recovery time (Pascoe et al., 2006).

Metabolism

The total body clearance of propofol is rapid and exceeds hepatic blood flow, suggesting extrahepatic metabolism (Veroli et al., 1992). Indeed, in one study performed in human patients undergoing liver transplantation, the amount of propofol metabolite excreted did not decrease when the liver was excluded from the circulation (Veroli et al., 1992) and the pharmacological effects are not different in patients with cirrhosis (Servin et al., 1990). The site of extrahepatic metabolism is unclear, but pulmonary tissue has been shown to contribute to propofol metabolism in cats (Matot et al., 1993). There may be significant species differences in the site and amount of extrahepatic metabolism.

Although awakening is generally attributed to redistribution, the termination of the effect of propofol is largely attributed to rapid and extensive biotransformation by the liver to inactive metabolites, which are excreted in the urine. In the dog the two major urinary metabolites of propofol are the glucuronide and sulfate conjugates of 4-hydroxypropofol (2,6-diisopropyl-1,4-quinol) (Hay Kraus et al., 2000). The formation of this intermediate derivative appears to be a critical initial step in the biotransformation and elimination of propofol in dog (Hay Kraus et al., 2000). It has also been shown that there are breed differences in metabolic enzyme pathways, which would account for the slower drug clearance seen in Greyhound and geriatric dogs (Reid and Nolan, 1996; Court et al., 1999; Hay Kraus et al., 2000). Although the amount of hepatic glucuronidation has not been studied in cats, there are reports of delayed recovery in cats after prolonged constant rate infusions of propofol, possibly due to the deficiency in cats of enzymes needed for glucuronidation (Pascoe et al., 2006).

Adverse Effects/ Contraindications

Propofol can cause local pain on injection, which is often worse in small peripheral veins. Some anesthetists will preferentially choose larger veins, administer through a running IV line, or administer a small volume of lidocaine IV immediately before administering propofol to prevent the pain on injection.

Propofol without preservative has been associated with increased wound infection. Retrospective analysis of dogs and cats with clean wounds showed an almost four times greater risk of postoperative infection in animals administered propofol (Heldmann et al., 1999). Strict aseptic technique should be emphasized when preparing and administering propofol and unused drug should be discarded within 24 hours (of the nonpreservative formulation). Surgeons performing surgery on patients anesthetized with propofol should be cognizant of this increased risk.

Because of the lipid emulsion, propofol has been suggested as a cause of postanesthetic pancreatitis. Pancreatitis associated with propofol has been reported, albeit rarely, in humans; it has not been reported in veterinary species (Gottschling et al., 2005). Furthermore, it is commonly used in patients with active pancreatitis (Herman et al., 2005).

Propofol syndrome is a rare but often lethal complication following a prolonged continuous administration of propofol. Patients can develop a metabolic acidosis, rhabdomyolysis, kidney injury, cardiac arrhythmias, and cardiac failure. The pathophysiology of this syndrome appears to involve a disturbance of mitochondrial metabolism induced by propofol (Trampitsch et al., 2006). Neonates and septic patients appear to have a greater risk of developing the syndrome. Any patient on a prolonged infusion of propofol should be monitored for these potential adverse signs.

Species Differences

Dogs: Propofol can be used for short or long-term sedation, induction of general anesthesia, and continuous rate infusions. The induction dose required for Greyhounds is not different from that required for mixed-breed dogs; however, the recovery time was longer for Greyhounds (see Section Metabolism).

Cats: Propofol can induce oxidative injuries to feline red blood cells when administered as an induction dose followed by a 30 minutes constant rate infusion. This can result in Heinz body formation, anorexia, diarrhea, and malaise (Andress et al., 1995). However, cats administered induction doses of propofol twice daily for 5 days did not show adverse hematological changes (Bley et al., 2007).

Equine: Propofol should not be used as a sole induction agent in horses as it is associated with excitement. The excitement is likely caused by the long time required to administer the large volume of drug, resulting in the display of stage II anesthesia (excitement stage). Following sedation with an α_{2}-agonist many horses still showed excitement at induction with propofol (Mama et al., 1996). Heavy sedation with guaifenesin has been shown to mitigate the excitement at induction (Brosnan et al., 2011).

The quality of recovery from propofol anesthesia horses is good (Mama et al., 1996; Posner et al., 2013). Although good recovery characteristics are important for horses, the presence of excitement during induction and the prohibitive cost for large patients make it unlikely that propofol will be routinely used in equine patients.

Pigs: Propofol does not trigger malignant hyperthermia in susceptible animals (Fruen et al., 1995). However, good sedation is necessary to provide reasonable venous access. Respiratory depression and apnea have been reported with propofol administration in pigs (Tendillo et al., 1996); thus, propofol should be used with caution unless intubation can be readily accomplished.

Bird: Propofol produces significant respiratory depression in red tailed hawks and great horned owls (Hawkins

Table 12.3 Propofol induction dose and constant rate infusion (CRI) dose for animals

Species	Induction dose (mg/kg IV)	CRI dosage (mg/kg/min IV)	Reference
Dog	3–7	0.2–0.6	
Cat	5–8	0.5–1.0	
Horse – adult	4–8		Mama et al., 1996
Horse – foal	2.0	0.33	
Donkey	2	0.21	
Pigs	2–3	0.1–0.2	Tendillo et al., 1996
Llama	3.3	0.4	del Alamo, 2014
Ferret	2–4		
Rabbit	2–10		

et al., 2003). It is reasonable to presume that all birds may need ventilatory assistance when anesthesia is maintained with propofol. CNS excitement has been noted at recovery (Hawkins et al., 2003).

Fish: Propofol has been used to produce anesthesia in fish both intravenously and via immersion (Fleming et al., 2003; Oda et al., 2014).

Dose

Propofol should be administered slowly to effect. The dose needed will depend on the type and dose of premedication, the health of the patient, and how painful the procedure will be. Premedicants that add CNS depression can decrease induction doses by more than 50%. Time of unconsciousness depends on premedicants and dose of propofol administered. Generally, unconsciousness last from 2–8 minutes. The doses listed in Table 12.3 are provided for the indicated species; however, each patient is different and the total dose should be titrated for a particular patient.

Drug Interactions, Compatibilities, and Incompatibilities

Propofol is compatible with 5% dextrose which can be used to dilute propofol for constant rate infusion. Propofol has been mixed with thiopental in a 1 : 1 solution. The mixture has been shown to be stable and provided smooth inductions that were similar to thiopental but better recoveries (more like propofol) (Ko et al., 1999).

Overdosage/acute toxicity: Accidental overdose of propofol can result in severe cardiovascular and respiratory depression. Treatment is supportive: intubation and ventilation, fluid therapy, positive inotrope, and/or vasoactive drugs. Fortunately, because of rapid recovery, the duration of effect is short.

Regulatory Information

Controlled drug status: Propofol is a nonscheduled (controlled) drug, but has been proposed to be placed in Schedule IV.

Withdrawal times: Withdrawal times have not been established for animals that produce food. However, FARAD recommends at least 72 hours for meat (Lin and Walz, 2014), but could not offer recommendations for milk due to lack of data.

Drug Availability

FDA Veterinary Approved Products

Rapinovet (Schering-Plough Animal Health Corp) 10 mg/ml in 20-ml vials
PropoFlo (Abbot Laboratories) 10 mg/ml in 20-ml vials
PropoFlo 28 (Abbot Laboratories) 10 mg/ml in 20 and 50-ml vials (for dogs only).

Human Products

Diprivan (Zeneca) 10 mg/ml in 20, 50, and 100-ml vials
Propofol (Hospira) 10 mg/ml.

Dissociative Anesthetics

History

Dissociative anesthetics (e.g., ketamine) have been used extensively in veterinary medicine and may still be the most common class of anesthetics in use. The first dissociative anesthetic used was phencyclidine hydrochloride (PCP, “angel dust”), which is no longer commercially available because of the abuse of this drug among humans. Newer phencyclidine derivatives include ketamine hydrochloride and tiletamine hydrochloride. Ketamine is also a drug of abuse in humans (“special-K”) and tiletamine is only marketed in combination with zolazepam under the trade name Telazol® or Zolatel®.

The term dissociative anesthetic originated from the use of ketamine in human patients. When anesthetized with ketamine, patients appeared to feel “dissociated” from or unaware of their environment, but did not always appear asleep (cataleptic). Later it was determined that these drugs did indeed dissociate the thalamocortical and limbic systems causing the change in awareness.

Aside from their use as general anesthetics, dissociative anesthetics are used as analgesics for acute and

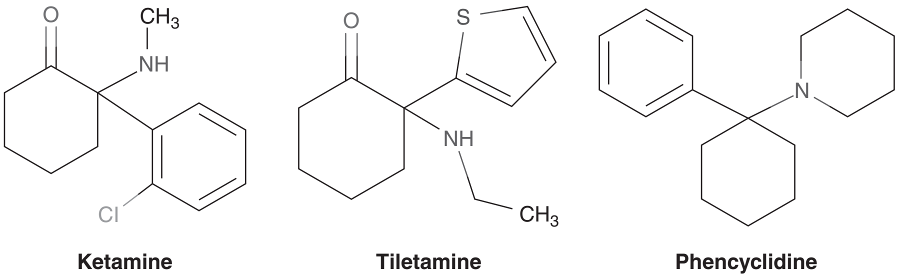

Figure 12.3 Structures of ketamine, tiletamine, and phencyclidine.

chronic pain states and as well as antidepressants (Stahl, 2013).

Classification

Chemistry: (Figure 12.3) Ketamine, 2-(o-chlorophenol)-2-(methylamino)-cyclohexanone hydrochloride, is a phencyclidine derivative that exists as a racemic mixture with the S (+) isomer having greater potency than the R (−) isomer (Casoni et al., 2014). The S (+) isomer produces more analgesia and less emergence delirium than the R (−) isomer.

Tiletamine, 2-[ethylamino]-2-[2-thienyl]-cyclohexanone hydrochloride, is a phencyclidine derivative.

How supplied: Ketamine is supplied as a 10%, aqueous solution (pH 3.5–5.5). It is preserved with benzethonium chloride.

Tiletamine is supplied only in combination with zolazepam as a white powder. The addition of 5 ml diluent produces a solution containing the equivalent of 50 mg tiletamine base, 50 mg zolazepam base, and 57.7 mg mannitol per milliliter. This solution has a pH of 2 to 3.5.

Mechanism of Action

Dissociative anesthetics are noncompetitive antagonists at *N*-methyl-D-aspartate (NMDA) receptors. These drugs prevent the binding of excitatory neurotransmitters, glutamate, and glycine at the NMDA receptor, preventing conduction of ions (Na^+, K^+, and Ca^{2+}). This prevents firing of the second-order neurons and results in depressed activity at the thalamocortical and limbic systems and depression of nuclei in the reticular activating system. Dissociatives also have weak effects at opioid receptors (mu > kappa), monoaminergic receptors, muscarine receptors, and sigma-1 receptors (endoplasmic reticulum calcium channels), but unlike many other induction agents do not interact with GABA receptors (Annetta et al., 2005; Stahl, 2013). Anesthesia with dissociatives produces an altered consciousness or catalepsy.

Unlike other induction agents, dissociatives anesthetics produce analgesia. Analgesia for acute pain is likely at least partially mediated through activation of mu opioids receptors (Sarton et al., 2001). Additionally, the NMDA receptor is also involved in the induction and maintenance of central sensitization in the dorsal horn of the spinal cord (Woolf and Thompson, 1991). Blocking the NMDA receptor with subanesthetic doses of ketamine can interrupt the central sensitization (Correll et al., 2004). Antagonism of the NMDA receptor has also shown great promise in the treatment of refractory depression; however, the mechanism of action as an antidepressant is unknown (Stahl, 2013).

Indications

Dissociative anesthetics can be used for chemical restraint, rapid induction of general anesthesia, and to provide analgesia (for both acute pain as well as interruption of central sensitization). They can be used in most species and can be administered intramuscularly and intravenously.

Physiological/Pharmacodynamic Effects

CNS effects: Based on EEG findings, the antagonism of NMDA receptors produces a dissociation of the thalamocortical and limbic systems (Reich et al., 2005). This produces an altered consciousness or catalepsy, where the patient does not appear asleep, but does not react to noxious or nonnoxious stimuli. Although patient may not look asleep, NMDA antagonists are effective at producing amnesia (Haas and Harper, 1992). When used alone, the dissociative anesthetics rarely produce a surgical depth of anesthesia, but when combined with other CNS depressants produce adequate relaxation and immobility.

The CNS effects of dissociatives are different than most other anesthetics. They increase CBF which is coupled with an increase in cerebral glucose metabolism and oxygen demand ($CMRo_2$) (Dawson et al., 1970). The increased CBF is caused by vasodilation of cerebral vessels and an increase in blood pressure, which results in an increase in ICP. Hypercapnia contributes to the rise in ICP and controlling ventilation can attenuate the rise in ICP. Thus, these drugs should be used with caution in any patient having or suspected of having elevated

ICP, or where cerebral metabolic demands may not be being met. The effects on ICP are also associated with increased intraocular pressure. Ordinarily, this is not a problem, but these agents should not be used in patients with glaucoma.

Ketamine causes the development of EEG patterns that are epileptiform (Kayama, 1982) and is used to elicit more robust seizures during electroconvulsive therapy (Krystal et al., 2003). Interestingly, there is also evidence that ketamine is anticonvulsive (Reder et al., 1980) as well as neuroprotective (Himmelseher and Durieux, 2005). However, most anesthesiologists recommend avoiding ketamine in patients with a seizure history and it should not be used in patients with elevated intracranial pressure.

Dissociative anesthetics cause an increase in norepinephrine via central adrenergic stimulation and a decreased reuptake of norepinephrine, resulting in an increase in sympathetic tone (Stoelting, 1999). The increase in norepinephrine affects all systems under adrenergic control (e.g., cardiovascular, respiratory, endocrine, etc.).

Emergence delirium (e.g., anxiousness, vocalization, thrashing) is a concern whenever dissociative anesthetics are used. Delirium may be merely unpleasant in smaller animals, but can be dangerous when used in larger animals (e.g., horses). Emergence delirium can be attenuated or prevented by administering dissociative anesthetics with sedatives or tranquilizers (e.g., xylazine, diazepam, acepromazine). The R (+) isomer of ketamine is associated with more delirious effects (Stoelting and Hillier, 2012).

Awakening from ketamine is primarily due to redistribution of drug, although some effects are from metabolism.

Cardiovascular system: Ketamine has direct myocardial depressant effects (Diaz et al., 1976) but its administration is generally associated with increase in cardiac output, mean aortic pressure, pulmonary arterial pressure, central venous pressure, and heart rate (Haskins et al., 1985). The stimulatory effects are due to directly stimulating the central adrenergic centers (i.e., increased sympathetic tone) and by inhibiting the neuronal uptake of catecholamines, especially norepinephrine (Annetta et al., 2005). The cardiovascular stimulation is associated with an increase in myocardial work and myocardial oxygen demands (Haskins et al., 1985), thus ketamine should be used with caution in patients with cardiovascular disease that cannot tolerate increased metabolic needs. Although the sympathetic stimulation overrides the direct cardiovascular depressant effects of ketamine (Adams, 1997), patients that are catecholamine depleted (i.e., critically ill) may show more of the cardiodepressive effects (Waxman et al., 1980).

The increased sympathetic tone also may cause tachycardia. Caution should be used with patients that are already tachycardic or dysrhythmic.

Ketamine preserves cardiovascular function and oxygen balance during experimentally produced septic shock (Van der Linden et al., 1990). This cardiovascular sparing effect may be due to the ability of ketamine to block the inflammatory cascade caused by endotoxins that depress cardiovascular function (Taniguchi and Yamamoto, 2005) as well as by increasing levels of norepinephrine that may attenuate the inappropriate peripheral vasodilation seen in septic patients.

Respiratory: Dissociative anesthetics generally have a mild effect on minute ventilation and therefore usually cause a moderate increase in carbon dioxide concentrations. This is in contrast to many other anesthetics that are potent respiratory depressants. However, when other CNS depressants are administered with ketamine, significant respiratory depression can be observed. Ketamine also can cause an *apneustic* pattern of breathing, which is characterized by a rapid sequence of breaths followed by breath holding on inspiration. This occurs more commonly with rapid IV administration of ketamine. Although apneustic breathing is unusual to watch, minute ventilation and carbon dioxide levels are generally within normal limits.

Ketamine has bronchodilating properties and decreases airway resistance (Durieux, 1995). This makes it useful as an induction drug for patients with clinical asthma as well as patients with obstructive airway disease (e.g., chronic obstructive pulmonary disease).

When ketamine is used as a sole anesthetic, pharyngeal and laryngeal reflexes remain active (Robinson et al., 1986). Preservation of these reflexes, however, leads to an increase risk of laryngospasm and coughing secondary to secretions or manipulation in the oropharynx. These complications make ketamine alone a poor drug for use in endoscopy or oropharyngeal surgery. Although laryngeal reflexes are preserved they can be uncoordinated, and thus aspiration is possible. Endotracheal intubation should be used to maintain and protect the airway.

Additionally, ketamine stimulates salivation, which can be copious at times. The administration of an anticholinergic agent (e.g., glycopyrrolate) for its antisialagogue properties can attenuate the amount of salivation. Caution should be exercised when using anticholinergics in patients with small airways as the antisialagogue properties can make for viscous secretions that can occlude the airways or endotracheal tube.

Upper airway muscle tone and reflexes are preserved when dissociatives are used alone. However, since these drugs are generally administered with muscle relaxants, laryngeal control is then diminished or absent.

Endotracheal intubation is recommended for all anesthetized patients to maintain and protect the airway.

Muscular effects: Dissociative anesthetics provide little muscle relaxation and may cause muscle rigidity, myoclonus, and/ or uncoordinated muscle movements. Muscle relaxation is generally provided by the coadministration of sedatives or tranquilizers (e.g., benzodiazepine, α_2-agonists).

Miscellaneous: The appearance of patients anesthetized with dissociative anesthetics is different than with most other anesthetics. Many patients do not close their eyes, can have muscle tone and muscle movement, and often do not look "asleep". It is important to protect the corneas of patients with adequate lubrication and prevent objects from rubbing on the cornea. Coadministration of sedatives or tranquilizers can attenuate these signs.

Analgesia: As described in the Mechanism of Action section, NMDA antagonists such as ketamine produce analgesia. For many years the dogma has been that ketamine provided greater somatic compared with visceral analgesia. However, this view is too simplistic to explain the varied analgesic effects and should be discarded. The mechanism for antinociception is complex and likely involves interactions at more than one type of receptor. Ketamine provides a use-dependent (i.e., works better when the nerves are stimulated) blockade of the NMDA receptor as well as inhibiting neurotransmitter release, both of which has been shown to mediate nociception (Annetta et al., 2005). Analgesia is also likely mediated by the action of ketamine on mu and kappa opioids receptors (Annetta et al., 2005). Opioid receptors extend beyond the CNS and spinal cord and occur in many peripheral tissues. Ketamine produces analgesia at subanesthetic doses for acute surgical pain and have opioid-sparing effects (Annetta et al., 2005).

Additionally, NMDA antagonists at subanesthetic doses are effective at treating chronic pain associated with central sensitization (wind-up pain), neuropathic pain (Guirimand et al., 2000), and likely other types of inflammatory pain. Ketamine by constant rate infusion has been successful in interrupting central sensitization. The duration of the infusion needs to be at least 24 hours, but at times, administration was continued for days to weeks before signs abated (Correll et al., 2004; Sigtermans et al., 2009). When ketamine is used at subanesthetic doses, behavioral changes are rarely seen.

Pharmacokinetics

Pharmacokinetic values for ketamine in various species are summarized in Table 12.4. Both ketamine and tiletamine are highly lipid soluble, so absorption is rapid from the intramuscular route with peak plasma concentration is reached in ~10 minutes (Baggot and Blake, 1976). Ketamine can also be absorbed through oral or rectal mucous membranes. This makes it possible to administer by spraying the drug in the mouth of fractious/feral animals or to administer rectally (Hanna et al., 1988). Cats administered ketamine orally often salivate profusely, presumably from the bitter taste or low pH or both. Cats administered ketamine rectally showed a slow smooth induction, no discomfort from this route of administration and a ~43% availability of drug (Hanna et al., 1988).

Metabolism

Ketamine: In most species, ketamine is biotransformed by the liver by *N*-demethylation to norketamine which then undergoes hydroxylation to form a water-soluble glucuronide derivative that is eliminated in urine (White et al., 1982; Stoelting and Hillier, 2012). Norketamine is an active metabolite of ketamine and has 10–30% activity of the parent drug (Leung and Baillie, 1986; Hanna et al., 1988). In the cat, because of deficiencies in some glucuronidation pathways, ketamine only undergoes transformation to norketamine which is excreted largely unchanged in the urine (Hanna et al., 1988). Since the active metabolites are excreted by the kidneys, decreased renal excretion may prolong the effects of the drug.

Telazol: Telazol is an equal mixture of tiletamine and zolazepam (a benzodiazepine), so the metabolism of this drug needs to be discussed in terms of the two drugs.

Table 12.4 Pharmacokinetics of ketamine in various species

Species	Dose (mg/kg IV)	Distribution phase (min)	Elimination half life (min)	Protein binding %	Clearance (ml/min/kg)	Reference
Dog	15	1.95	61	53.5	32.2	(Kaka et al., 1979)
Cat	25	2.7	78.7	53	21.3	(Hanna et al., 1988)
Horse	2.2	2.9	42	50	26.6	(Kaka et al., 1979)
Calf	5.0	6.9	60.5		40.4	(Waterman, 1984)
Humans	2.2	4.68	130	60		(Domino et al., 1984)

In cats, the duration of effect of zolazepam exceeds that of tiletamine so that, with time, the pharmacodynamic effect is that of the benzodiazepine tranquilization (Telazol Product-Literature, 2017). In dogs, the duration of effect of tiletamine exceeds that of zolazepam so that, with time, the pharmacodynamic effects reflect the dissociative anesthetic, including muscle rigidity, sympathetic stimulation, and emergence delirium (Telazol Product-Literature, 2017). Other species have similar disparities in metabolism and recoveries from Telazol. Pigs awaken slowly and calmly, whereas horses can have an agitated recovery if not provided with additional sedation. Reversal of the zolazepam in animals with a benzodiazepine antagonist can lead to an anxious recovery if sufficient plasma levels of tiletamine are still present.

Adverse Effects/ Contraindications

CNS disease: Ketamine/ tiletamine should not be used in animals with elevated intracranial pressure.

Pain from injection: Ketamine is a hydrochloride salt, which must be kept at a low pH to maintain solubility. The pH of ketamine is 3.5 which can cause some irritation and pain during IM injections (Hanna et al., 1988).

Cardiovascular disease: Ketamine/ tiletamine should be used with caution in patients with coronary artery disease, uncontrolled arterial hypertension, cardiomyopathy, or heart failure.

Emergence delirium: Caution should be used in patients where emergence delirium could be injurious to the patient or to medical personnel (e.g., horse). Emergence delirium can be prevented or attenuated by coadministration of sedatives or tranquilizers. In general, dissociative anesthetics should not be administered as sole agents.

Ocular disease: Ketamine/ tiletamine should not be used animals with elevated intraocular pressure or with an open globe injury due to the rise in intraocular pressure following administration.

Increased sympathetic tone: Ketamine/ tiletamine should be avoided in patients with high sympathetic tone such as hyperthyroidism or pheochromocytoma since administration of these drugs can increase norepinephrine levels and exacerbate the side effects of these diseases.

Urethral obstruction or renal insufficiency: Caution should be used in patients where excretion of the active metabolites may be decreased, such as cats with urethral obstruction or anuric renal failure.

Table 12.5 Dose of ketamine and tiletamine in various species

Species	Dosage of ketamine (mg/kg)[a]	Dosage of Telazol® (mg/kg) [b]
Dog	2–5 IV, 5–10 IM	3–6 IM
Cat	5–10 IV, 5–10 IM 10–20 PO 25 rectally	4–7 IM
Cattle	2–4 IV	2–4 IV
Camelid	2–4 IV	0.5–2 IV, 2–4 IM
Ferret	2–5 IV, 5–10 IM	
Horses	2 IV	1–3 IV (following α_2-agonist)
Rat	40–80 IM	30–60
Pigs	10–30 IM	6 IM (following α_2-agonist) 0.01–0.02 ml/kg as TKX[d]
Rabbits	20–50 IM	30–60 IM[c]
Primates	2–4 IV, 10–15 IM	3 IM

[a] Following sedation with benzodiazepine, α_2-agonist or phenothiazine.
[b] Dose for Telazol is for combination of drugs at 100 mg/ml.
[c] Telazol® should not be used in New Zealand White Rabbits.
[d] TKX = 500 mg Telazol® (as powder) + 250 mg ketamine + 250 mg xylazine.

Dose

Dose ranges for ketamine and tiletamine in various species are listed in Table 12.5.

The volume per kg of body weight of Telazol is less than an equipotent amount of ketamine. This makes it attractive for work with zoo/ wildlife animals where the volume may be important (e.g., darts or syringe poles).

Species Differences

Horse: Horses should not be administered dissociative anesthetics as single agents due to the lack of muscle relaxation and recovery delirium. Telazol in particular can be associated with rough anesthetic recoveries and should be balanced with the use of additional sedatives or tranquilizers, before induction and before recovery.

Tigers: Great controversy occurs over the use of Telazol in the large cats and in tigers specifically. Although there is little published evidence, many anesthesiologists and zoo medicine specialists caution against the use of Telazol in the large cats (Tilson, 1994; Muir et al., 2000; Morris, 2001). Reported complications have ranged from slow ataxic recoveries to delayed (2–4 days after anesthesia) neurological dysfunction, including hind limb weakness, drowsiness, hyperreflexia, hyperresponsive behavior, twitches, seizures, and death (Tilson, 1994; Klein, 2007; Lewis, 2007).

Rabbits: At clinical doses, tiletamine (the dissociative part of Telazol) causes lethal renal tubular necrosis in New Zealand White rabbits (Doerning et al., 1992). Other rabbit species appear unaffected.

Pigs: A combination known as TKX (Telazol, ketamine, xylazine) is commonly used to anesthetize pigs. The mixture is composed of 500 mg (as powder) Telazol, 250 mg ketamine, and 250 mg xylazine. Due to slow zolazepam metabolism, pigs can have prolonged recoveries after TKX.

Use of ketamine in animals susceptible to malignant hyperthermia has been controversial; however, ketamine did not induce malignant hyperthermia in 76 susceptible pigs (Dershwitz et al., 1989).

Drug Interactions

The concurrent administration of other CNS depressants can increase respiratory and cardiovascular depression. Chloramphenicol can prolong recovery times from ketamine (Amouzadeh et al., 1989) as well as from Telazol.

Overdosage/Acute Toxicity

Ketamine has a large therapeutic index; therefore, treatment of an overdose is primarily supportive care and addressing side effect such as respiratory or cardiovascular depression, muscle rigidity, emergence delirium, or adrenergic stimulation. There is no direct antagonist for ketamine or tiletamine. Other sedatives and muscle relaxants are used to manage the problems from an overdose until the drug is cleared.

Regulatory Information

Withdrawal time: Ketamine extra label use: at least 3 days for meat and 48 hours for milk.

Controlled drug schedule:

Ketamine is a Schedule III Controlled Drug.
Telazol is a Schedule III Controlled Drug.

Drug Availability

FDA Veterinary Approved Products

Ketamine is approved by the FDA for IM use in the cat and nonhuman primates: KetaFlo, Abbot Laboratories 100 mg/ml.

Telazol is approved by the FDA for IM use in dogs and cats (restricted during pregnancy): Telazol, Fort Dodge Animal Health, Division of Wyeth, 50 mg/ml Tiletamine and 50 mg/ml zolazepam/ ml of solution.

Human Approved Products

Ketalar, Parkedale Pharmaceuticals, 10 mg/ml, 50 mg/ml, 100 mg/ml.

Ketamine Hydrochloride, Hospira, 50 mg/ml, 100 mg/ml.

Etomidate

History

Etomidate was first introduced into human anesthesia practice in 1972. At the time it was considered close to the "ideal anesthetic" because of its ability to maintain hemodynamic stability, minimally depress the respiratory centers, and by having a large therapeutic index (i.e., the lethal dose/ effective dose). However, the ideal anesthetic has yet to be found and etomidate too has untoward side effects.

Classification

Etomidate is a nonscheduled, nonbarbiturate compound suitable for rapid intravenous anesthetic induction.

Chemistry: Etomidate is an ethyl ester of a carboxylated imidazole compound with a chemical formula of *R*-(+)-pentylethyl-1*H*-imidazole-5 carboxylate sulfate (Figure 12.4). The imidazole component allows for differing solubility at different pH concentrations. At a low (acidic) pH, etomidate is water soluble, but becomes lipid soluble at physiological pH. There are two isomers but only the (R)(+) isomer has anesthetic properties.

How supplied: Etomidate is poorly water soluble but highly soluble in alcohol, thus is supplied as a 2 mg/ml solution in 35% propylene glycol at a pH of 6.0. When

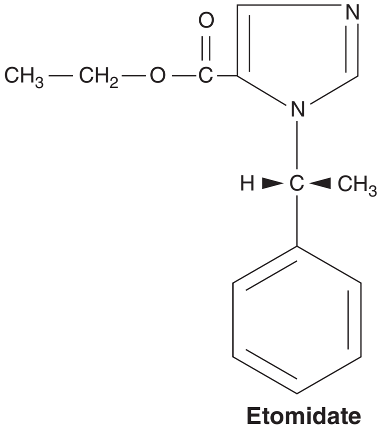

Figure 12.4 Etomidate.

supplied in propylene glycol, etomidate has an osmolarity of ~4620 osmole.

Mechanism of Action

Etomidate is an agonist at the γ-aminobutyric acid (GABA) receptor ($GABA_{Aß3}$) producing hypnosis and CNS depression by enhancing the effects of the inhibitory neurotransmitter GABA (O'Meara et al., 2004). Binding of GABA to the receptors increases chloride binding, resulting in hyperpolarization of the post synaptic neuron and a decrease in neurotransmission.

Indications

Etomidate is indicated for the rapid intravenous induction of anesthesia, particularly in patients with cardiovascular instability.

Physiological Effects

CNS effects: Etomidate is considered cerebral friendly because it results in decreased ICP, decreased CBF, and decreased cerebral metabolic rate for O_2 ($CMRo_2$). Since the MAP is essentially unchanged, this results in a favorable metabolic state for the CNS; the cerebral perfusion pressure is increased as is the cerebral oxygen supply : demand ratio. The EEG quiets (similar to the barbiturates), but there can be increased EEG activity at epileptogenic foci. Grand mal seizure have been reported, and some anesthetists argue against its use in patients with a known seizure history (Bergen and Smith, 1997).

Due to similar mechanisms, the intraocular pressure is also decreased. Intraocular pressure can decrease by up to 60% but the effect lasts for only for ~5 minutes.

Cardiovascular system: Etomidate is unique amongst most intravenous general anesthetics in that it causes minimal hemodynamic changes and thus maintains cardiovascular function. At routine induction doses, etomidate causes minimal changes in stroke volume (SV), MAP, cardiac index (CI), pulmonary artery pressure (PAP), pulmonary arterial wedge pressure (PAWP), central venous pressure (CVP), or systemic vascular resistance (SVR) (De Hert et al., 1990). In addition to causing minimal CV derangements, the baroreceptor and sympathetic nervous system reflexes remain intact, which also contributes to hemodynamic stability. Etomidate is not arrhythmogenic, does not sensitize the heart to catecholamine, and it does not cause histamine release. It is the most commonly used induction agent in dogs having pacemaker implantation (Sanchis-Mora et al., 2014).

Respiratory: Etomidate can cause respiratory depression. Induction doses can result in brief periods of apnea, but generally arterial carbon dioxide partial pressure ($Paco_2$) is only slightly increased if affected at all. Arterial oxygen (Pao_2) is generally unaffected. However, when etomidate is administered with other drugs that can affect CNS function, more respiratory depression can be seen. Since etomidate has limited effect on muscle relaxation, airway reflexes are generally maintained. Intubation, however, is highly recommended.

Endocrine system: In the early 1980s it was noted that there was increased morbidity and mortality in patients sedated long term (e.g., patients on ventilators) with etomidate due to a decreased cortisol production (Wagner et al., 1984). Etomidate causes a reversible inhibition of the enzyme 11-beta-hydroxylase (Figure 12.5), which is an integral part of the pathway that converts cholesterol to glucocorticoids and mineralocorticoids. The resultant decrease in cortisol, corticosterone, and aldosterone production raises concern for patients' ability to respond to stress. Following induction with etomidate, suppression of the adrenal–cortical axis is depressed for up to 6 hours in dogs and 3 hours in cats (Dodam et al., 1990; Moon, 1997). Single induction doses do not cause clinical problems associated with steroid production, but care should be taken with patients with preexisting adrenal–cortical diseases (e.g., hypoadrenocorticism), or who might have relative hypoadrenocorticism, or adrenal depression from chronic disease. Furthermore, extended periods of use (e.g., constant rate infusions) are not recommended due to suppression of cortisol production (as well as the hyperosmolarity of the solution).

Muscular effects: Etomidate does not provide significant muscle relaxation. Muscle rigidity and myoclonus can be seen at, and following, induction but is not associated with seizure-like EEG activity. The use of muscle relaxants (e.g., benzodiazepines) can minimize the incidence and intensity of the muscle movements (Doenicke et al., 1999) and is routinely recommended. Etomidate can potentiate the effects of nondepolarizing neuromuscular blockers.

Analgesia: Etomidate does not provide any analgesia. If patients are anesthetized to facilitate surgery or painful procedures, analgesia must be provided separately with other agents (e.g., opioids, α_2-agonist).

Pharmacokinetics

Following intravenous administration, etomidate is rapidly distributed into the CNS to produce anesthesia. Etomidate is 75% bound to plasma proteins. Three compartment pharmacokinetic models have been used

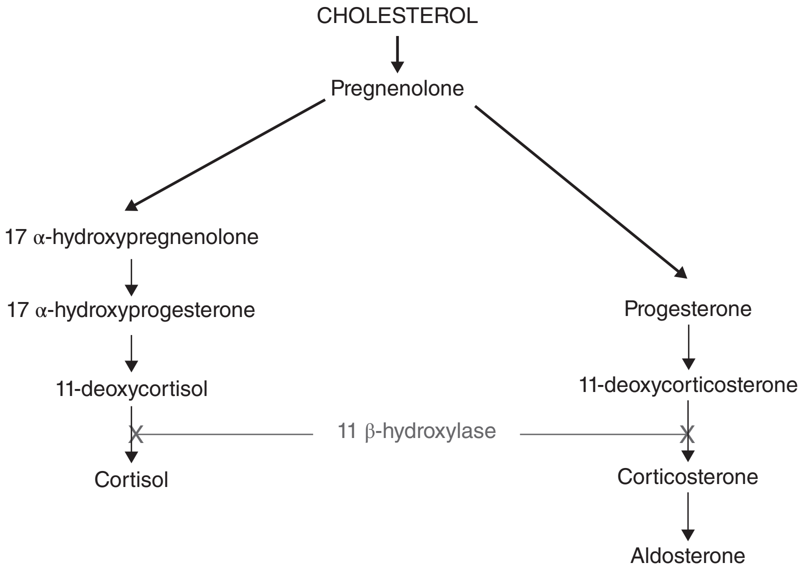

Figure 12.5 Pathway for cortisol and aldosterone production affected by action of etomidate.

to describe etomidate disposition in animals. It has a short redistribution half-life (29 minutes in humans; 22 minutes in cats) and a large steady-state volume of distribution (2.5–4.5 l/kg in humans; 4.9 l/kg in cats). The elimination half-life varies from 2.9 to 5.3 hours in humans and is 2.9 hours in cats (Wertz et al., 1990). Redistribution of etomidate into body tissues is responsible for awakening and recovery time from anesthesia is similar to thiopental, but slower than propofol.

Metabolism

In humans, etomidate is 98% metabolized by liver (2% excreted unchanged in urine) by hydrolysis or glucuronidation via plasma esterases and hepatic microsomal enzymes. Metabolites are inactive and excreted in the urine (85%) and bile and feces (15%). Etomidate should be used cautiously in patients with liver disease as metabolism can be prolonged.

Adverse Effects/ Contraindications

Adverse effects of adrenocortical suppression and myoclonus have been discussed above. Other adverse effects of etomidate arise from the propylene glycol vehicle. The intravenous injection of propylene glycol can be painful. Pain can be minimized by administering etomidate through a running IV line or by injecting lidocaine (dog) through the catheter before induction. Furthermore propylene glycol causes the solution to be hyperosmotic (~4620 Osm) compared to plasma (~300 Osm), and thus etomidate has been associated with intravascular hemolysis (Moon, 1994). Clinically relevant hemolysis has been reported following prolonged administration (i.e., constant rate infusions) in dogs (Ko, 1993; Moon, 1994). Etomidate has been prepared in a lipid vehicle (Etomidate-lipuro, Braun, Germany) instead of propylene glycol, but it is not available in the United States.

Dose (Box 12.2)

Etomidate has wide safety margin, due to a large therapeutic index of 16 (i.e., lethal dose is 16 times the hypnotic dose) compared to the therapeutic indexes for propofol and thiopental (3 and 5, respectively). Etomidate should be titrated intravenously “to effect”. The wide dose range reflects the additive and sometimes synergistic effects of many premedications (e.g., opioids, benzodiazepines, phenothiazines). As discussed previously, etomidate should be administered following an adequate premedication. Duration of anesthesia is directly related to dose. Constant rate infusions are not recommended due to the potential for adrenocortical suppression and hemolysis (see Section Adverse Effects/ Contraindications).

Species Differences

Cats: Due to the extensive liver metabolism of etomidate and fragility of feline red blood cells, cats may be more likely to have clinical hemolysis following etomidate administration.

Box 12.2 Dose for etomidate in animals

Dogs: 0.5–4.0 mg/kg IV
Cats: 0.5–4.0 mg/kg IV
Pigs: 2–4 mg/kg IV
Mice: 11 mg/ kg IV; 24 mg/kg IP

Dogs: Clinical hemolysis has been seen following constant rate infusions.

Swine: Etomidate did not trigger malignant hyperthermia in susceptible pigs (Suresh and Nelson, 1985).

Drug Interactions

Concurrent use of other drugs that depress the CNS (e.g., barbiturates, opioids, general anesthetics, etc.) can potentiate the effects of etomidate.

Overdosage/Acute Toxicity

Acute overdoses would be expected to cause enhanced pharmacological effects of the drug. Treatment would be supportive (i.e., mechanical ventilation), until the effects of the medication are diminished.

Storage/Stability/Compatibility

Unless otherwise labeled, store etomidate injection at room temperature and protect from light.

Regulatory Information

Controlled drug status: Etomidate is a nonscheduled drug.

Drug Availability

FDA veterinary approved products

None

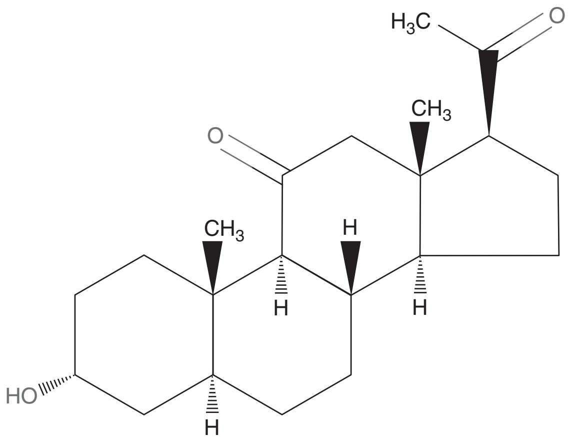
Human approved products

Etomidate Injection 2 mg/ml in 10 ml, 20 ml ampules, single use vials and 20 ml Abboject Syringes; Amidate® (Hospira); generic (Bedford); (Rx).

Neurosteroid Anesthetics

History

Synthetic neuroactive (nonhormonal) steroids have been intermittently popular in human and veterinary anesthesia since the 1970s. Althesin and Saffan® were mixtures of two neurosteroids, alfaxalone and alphadolone, which were used in Canada and the United Kingdom. Although these drugs produced anesthesia, significant side effects due to the solubilizing agent (chromophore) limited their popularity. Both products have been removed from the market. Specific information regarding these products can be found in previous editions of this book.



Alfaxalone

Figure 12.6 Alfaxalone.

Alfaxalone as a single agent was reintroduced into veterinary practice in Australia and United Kingdom in 2000 and has become a popular anesthetic in veterinary medicine. It was approved by the FDA for use in animals in 2014. There is no equivalent human product available.

Classification

Chemistry: Alfaxalone (3-alpha-hydroxy-5-alpha-pregnane-11,20-dione) is a steroid compound (Figure 12.6).

How supplied: Alfaxan®: Each ml contains 10 mg alfaxalone (1%) in 2-hydroxypropyl-beta cyclodextrin. Alfaxalone is highly lipophilic and therefore difficult to solubilize in water-based solutions. Alfaxan-CD inserts the alfaxalone molecule within a cyclodextrin (sugar) structure (Figure 12.7) to allow solubilization in water. Once administered, the dextran is metabolized and the free alfaxalone is bioavailable. The solution has a pH of 6.5–7.0 and has no preservative. The manufacturer recommends that unused product be stored in sterile syringes and unused drug discarded 6 hours after the bottle is opened.

Mechanism of Action

Neuroactive steroids enhance the effects γ-aminobutyric acid (GABA) at the $GABA_A$ receptor. Enhanced activation of the GABA receptors increases transmembrane chloride conductance resulting in hyperpolarization of the postsynaptic cell membrane, which causes inhibition of the postsynaptic neuron. This results in inhibition of pathway activation controlling arousal and awareness.

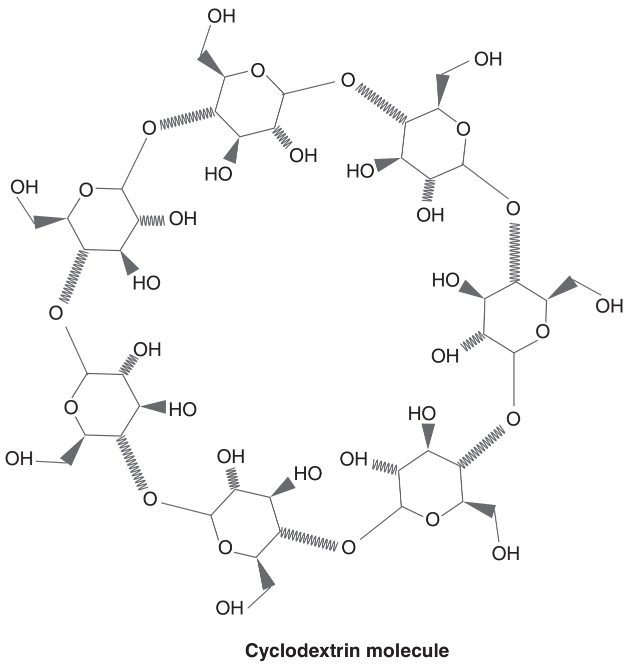


Figure 12.7 Cyclodextrin molecule used for complexing alfaxalone.

Indications

Alfaxalone is indicated for the intravenous induction of general anesthesia in dogs and cats.

Physiological/ Pharmacodynamic Effects

CNS effects: Neurosteroids produce unconsciousness and anesthesia along with a dose-dependent decrease in EEG activity (Zattoni et al., 1980). They produce a favorable neurological environment by decreasing cerebral blood flow, intracranial pressure, and cerebral metabolic demands (Rasmussen et al., 1978).

Cardiovascular system: Alfaxalone decreases arterial blood pressure and systemic vascular resistance (Rodríguez et al., 2012). Although the blood pressure changes are mild and generally not clinically relevant (Muir et al., 2008), the blood pressure in cats may be more affected (Muir et al., 2009). The decrease in blood pressure is associated with an increased heart rate and increased cardiac index (Rodríguez et al., 2012). Administration of alfaxalone with general anesthetic gases (e.g., isoflurane) can result in clinically relevant hypotension.

Respiratory: Alfaxalone is associated with a dose-dependent respiratory depression that may progress to apnea (Muir et al., 2008). All patients administered alfaxalone must be monitored for the need for endotracheal intubation and ventilatory support.

Muscular effects: Alfaxalone provides good muscle relaxation when used alone and is associated with good quality inductions and recoveries (Rodríguez et al., 2012).

Cesarean section: Anesthesia with alfaxalone is associated with good puppy viability following cesarean section and is associated with better APGAR scores in puppies compared with dogs anesthetized with propofol (Doebeli et al., 2013).

Miscellaneous: Perivascular injection does not cause tissue damage nor does it appear to be painful. Alfaxalone does not bind glucocorticoid, mineralocorticoid, or sex hormone receptors. There is no evidence that it clinically interferes with mineralocorticoid or glucocorticoid production. Alfaxalone has been successfully used in dogs and cats less than 12 weeks of age (O'Hagan et al., 2012), but has not been evaluated in kittens less than 4 weeks old or puppies less than 10 weeks old.

Allergic reactions: Earlier versions of the neurosteroid formulation were associated with allergic reactions ranging from erythema and edema to life-threatening anaphylaxis associated with the vehicle, which contained Cremophor. Further information regarding these reactions may be found in older editions of this book. Complexing with cyclodextrin to maintain solubility for injection has apparently solved this problem with adverse reactions, and currently marketed alfaxalone in a cyclodextrin molecule does not appear to cause allergic reactions in dogs or cats (Ferré et al., 2006).

Analgesia: Neurosteroids do not produce analgesia mediated through GABA_A receptors (Nadeson and Goodchild, 2000).

Pharmacokinetics

See Box 12.3 (Goodwin et al., 2011).

Box 12.3 Alfaxalone pharmacokinetics

Species	Half-life (min)	Volume of distribution (l/kg)	Dose IV^{a} (mg/kg)
Dogs	34	2.0	1–3
Cats	43	1.3	2–5
Horses	33.4	1.6	

[a] To effect.

Metabolism

Alfaxan is metabolized in the liver and eliminated in the bile and urine (Jurox Limited, 2014), as has been reported for other neurosteroids (Strunin et al., 1977).

Adverse Effects/ Contraindications

As with all CNS depressants, patients should be individually assessed for risks associated with anesthesia, myocardial depression, and ventilatory depression. Combining of CNS depressants can result in synergistic effects and make detrimental side effects more likely (e.g., hypoventilation).

Administration

The dose of alfaxalone (Box 12.3) should be titrated for each patient. It should be slowly administered IV until the patient is anesthetized ("to effect"). Administration of other CNS depressants as premedications will reduce the total amount of alfaxalone needed.

Although considered an off label administration route, intramuscular and subcutaneous (Heit et al., 2004) injection of alfaxalone will produced deep sedation. However, recovery following IM injection of alfaxalone is associated with excitability in cats even with adjunct sedation (Grubb et al., 2013).

Species Differences

Dog: Alfaxalone is a reasonable alternative to propofol in Greyhound dogs. Pharmacokinetics in Greyhound dogs were no different than Beagle dogs (Pasloske et al., 2009).

Horses: Alfaxalone has been used to produce general anesthesia in horses following premedication with acepromazine, xylazine, and guaifenesin. Induction scores with this protocol were good and the recoveries were considered satisfactory (Goodwin et al., 2011).

Alpaca: Alfaxalone produced general anesthesia with good inductions in alpaca; however, its use as a solo anesthetic agent was associated with poor anesthetic recoveries (Del Álamo et al., 2014).

Sheep: Alfaxalone produced anesthesia at 2 mg/kg IV with minimal cardiovascular effects, no reported apnea, and good recoveries (Andaluz et al., 2012).

Rabbits: Alfaxalone at 2–3 mg/kg IV produced anesthesia in rabbits, but was associated with apnea of ~45 seconds (Grint et al., 2008).

Overdosage/Acute Toxicity

Alfaxalone has a large therapeutic index and a short duration of action (Ferré et al., 2006). Alfaxalone has been administered at 10 times and five times the recommended dose in dogs and cats, respectively, with only the need for ventilatory support for full recovery (Muir et al., 2008; Muir et al., 2009). The half-life is short (Box 12.3), therefore adverse effects should dissipate quickly because of rapid elimination. Treatment of an overdose should focus on supportive care, particularly of the respiratory system, until recovery occurs.

Regulatory Information

Controlled drug status: Alfaxalone is a schedule IV drug.

Withdrawal information: No information available.

Drug Availability

Alfaxan (alfaxalone, 10 mg/ml): Jurox Inc. American Century Tower II, Kansas City, MO.

Human Products

None available

Miscellaneous Anesthetics

Alpha-Chloralose

History

Alpha-chloralose is a compound from the mixture of glucose and chloraldehyde. It has been used for sedation and immobilization of animals since the turn of the 20th century. It currently is not approved for use by the FDA; however, under FDA regulation it can be used in a variety of species. It is most commonly used in laboratory animal medicine, but has also been used to sedate wild (nuisance) birds to allow aesthetic removal from unwanted places (e.g., parks, schools, etc.)(O'Hare et al., 2007).

Chemistry

Chloralose, 1,2-O-(2,2,2-trichloroethylidene)-alpha-D-glucofuranose (Figure 12.8), is prepared by condensing anhydrous glucose with chloraldehyde (chloral) in the presence of sulfuric acid. A mixture of α-chloralose and β-chloralose is formed, of which the α-chloralose form is the active form. Chloralose is difficult to dissolve in an aqueous medium without simultaneous heating, but the solution should not be boiled.

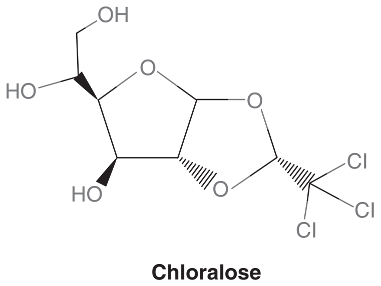

Figure 12.8 Chloralose.

Box 12.4 Chloralose doses in various species (administered as a single dose)

Dog	40–110 mg/kg IV
Cat	40–80 mg/kg IV
Sheep	45–55 mg/kg IV
Pig	55–86 mg/kg IV
Waterfowl	30 mg/kg PO
Pigeons	180 mg/kg PO
Other birds	15–50 mg/kg PO

How supplied: Alpha-chloralose usually is prepared and administered intravenously in 1% concentration. It has also been used orally in a variety of wild bird species (turkeys, pigeons, geese, etc.).

Mechanism of Action

The mechanism of action has not been identified. An active metabolite of α-chloralose, trichloroethanol, is the same as for the sedative, chloral hydrate. It is likely that both have interaction at the GABA receptor (see section on chloral hydrate later in this chapter)(Garrett and Gan, 1998).

Indication

Alpha-chloralose is best used as a sedative or hypnotic as it is not a complete general anesthetic. α-chloralose is restricted to terminal studies in laboratory animals in which recovery from anesthesia is not necessary. It is used often used in physiological experimentation because it purportedly does not interfere with respiratory and cardiac reflexes, for example, baroceptor and chemoceptor activities. It can also be used to sedate wild birds to allow for capture.

Physiology

Chloralose induces prolonged hypnosis, lasting up to 8–10 hours. It is metabolized to chloraldehyde or chloral, which is mainly transformed into trichloroethanol (a metabolite of chloral hydrate). Hypnosis and anesthesia produced by chloral hydrate and chloralose are quite similar because of the formation of same metabolite, trichloroethanol.

Alpha-chloralose was considered an ideal drug for sedation/anesthesia of research animals due to its purported ability to provide CNS depression while not depressing baroreceptor reflexes, vasomotor centers, or spinal reflexes. However, this is been shown to be untrue in rats, lambs, and rabbits (Fish and Meyer, 2008). Additionally, spinal reflex activity may increase to the degree that muscle activity ("convulsions") similar to those of strychnine poisoning develop in the dog and cat (Lees, 1972). Paddling movements and muscle fasciculations have been seen in pigs, sheep, and other species. Surgical anesthesia cannot be reached by administration of chloralose alone.

The degree of CNS depression that is produced by the drug is unknown. When α-chloralose overdose has occurred in people, they show marked CNS depression, with depressed to flat EEG waves (Manzo et al., 1979). Furthermore, people showed respiratory depression, muscle fasciculations, and seizure-like activity, similar to what had been reported in the dog (Lees, 1972; Manzo et al., 1979). Its effectiveness as an anesthetic varies among species, and is least effective in the dog. It is not recommended for survival procedures because of rough induction, prolonged recovery, and seizure-like activity (Silverman and Muir, 1993).

There is no evidence that α-chloralose provides analgesia and should not be used as single agents for surgical interventions (Silverman and Muir, 1993).

Intraperitoneal injections produce pain and inflammation and are not recommended.

Dose

See Box 12.4

Regulatory Information

Controlled drug status: Nonscheduled drug.

Drug Availability

There are no FDA Veterinary Approved nor Human Approved products.

Urethane

History

Urethane was a popular anesthetic for laboratory animals because it produces a long duration from a single administration and minimal physiological effects. It is no longer recommended because it is carcinogenic; however, it is still used for laboratory animal research (Lucking et al., 2014).

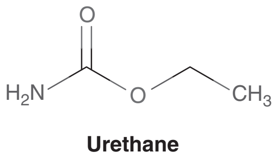

Figure 12.9 Urethane.

Chemistry

Urethane (ethyl carbamate) is the ethyl ester of carbamic acid (Figure 12.9). It is chemically related to urea and is readily soluble in water and alcohol.

Mechanism of Action

The mechanism of action of urethane has been poorly studied. It has been shown in rats that urethane selectively alters potassium currents to depress neuronal excitability (Sceniak and MacIver, 2005). This is a unique mechanism for an anesthetic.

Physiological Effects

Urethane produces long-lasting unconsciousness of 8–10 hours duration after a single dose. Spinal reflexes, neural transmission, and cardiopulmonary function are minimally affected. Unlike chloralose, urethane appears to induce analgesia and muscle relaxation. Urethane has been administered by most routes, including topically to frogs.

Metabolism

Urethane is metabolized slowly by cytochrome P450 into vinyl carbamate, vinyl carbonate epoxide, and eventually into CO_2 and NH_3. The rate of elimination is slow is associated with long difficult recoveries.

Carcinogenicity

Urethane is on the National Institute of Health's list of drugs that are "reasonably anticipated to be a human carcinogen" (USPHS, 2014). Exposure can be by inhalation, ingestion, or dermal contact. Strict precautions should be taken to prevent exposure to personnel.

Dose

Urethane is not recommended for used due to its potential as a carcinogen and because there are alternative anesthetics available. Rodents: 1 g/kg IV, 1–2 g/kg IP.

Regulatory Information

Controlled drug status: Nonscheduled drug

Drug Availability

There are no FDA Veterinary Approved nor Human Approved Products

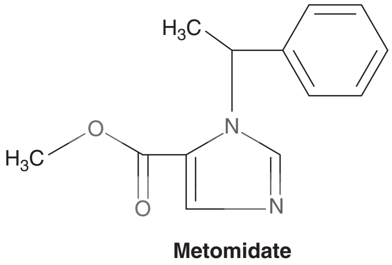

Figure 12.10 Metomidate.

Metomidate

History

Metomidate is a nonbarbiturate imidazole anesthetic that is in the same family as etomidate. It had been used as an anesthetic in mammals and birds, but currently is primarily used as a fish anesthetic. Because of a similar spelling, it has erroneously been confused with medetomidine (see Chapter 14), but they are very different agents.

Chemistry

Metomidate (methyl 1-(alpha-methylbenzyl)imidazole-5-carboxylate) is an imidazole compound (Figure 12.10).

How Supplied

Metomidate is white powder soluble in water and ethanol. It needs to be reconstituted in aqueous solutions, which are acidic.

Mechanism of Action

Imidazole anesthetics are γ-aminobutyric acid (GABA) receptor agonists that produce anesthesia and amnesia (Stoelting and Hillier, 2012).

Indications

Metomidate is primarily used to produce anesthesia in finfish.

Pharmacokinetics

Metomidate was rapidly absorbed over the gills and produced anesthesia within 1 minute at exposure to 9 mg/l (Hansen et al., 2003). Oral bioavailability in turbot fish was 100% (Hansen et al., 2003).

Physiology

Metomidate produces hypnosis, anesthesia, and muscle relaxation. Cardiovascular function is generally preserved, but respiratory depression and apnea can occur. They are poor muscle relaxants and provide no analgesia.

Imidazoles (metomidate and etomidate) have been credited with providing complete anesthesia and decreasing the stress response. Unfortunately, the stress-free aspects attributed to these drugs are a complete misnomer. Metomidate blocks the 11-beta hydroxylation of cortisol both in mammals and in fishes. This seriously perturbs the complex positive and negative feedback pathways for control of the neuroendocrine cascade. It is therefore likely that animals are experiencing the same stress, but are not able to respond to it by producing cortisol. Researchers should be cautious in interpreting stress response in animals exposed to imidazole anesthetics.

Fish exposed to metomidate can have dark skin discoloration after exposure. Because cortisol inhibits the release of adrenocorticotrophic hormone (ACTH) and ACTH stimulates melanocyte stimulating hormone, it is hypothesized that the decrease in cortisol production that occurs with the use of these drugs results in an increase in melanocyte stimulating hormone (Harms and Bakal, 1994).

Doses

Aquacalm^{TM}: Immersion agent for fish. The dose for sedation is 0.1–1.0 mg/l, and the dose for anesthesia is 1.0–10 mg/l.

Species Differences

Frogs: Leopard frogs exposed to metomidate by immersion in 30 mg/l became sedated, but only 27% became anesthetized (Doss et al., 2014). Furthermore, recovery times were extremely prolonged (up to 5 hours)(Doss et al., 2014).

Regulatory Information

Metomidate is a noncontrolled drug.

Drug Availability

FDA veterinary approved products: Aquacalm^{TM} is legally marketed as an FDA indexed product under MIF 900-002 (Western Chemical Inc., 2009). It is approved for ornamental finfish only. Each gram of Aquacalm^{TN} contains 1 gram of metomidate hydrochloride. Available in 1, 5, 10, 50-gram bottles

Human approved products: None

Tribromoethanol

History

Tribromoethanol is an injectable anesthetic agent used in mice. It was manufactured as Avertin® but this product is no longer available. Investigators who wish to use tribromoethanol as an anesthetic must make their own solutions.

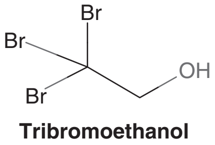

Figure 12.11 Tribromoethanol.

Chemistry

2,2,2-Tribromoethanol (Figure 12.11).

Mechanism of Action

Tribromoethanol interacts with the GABA$_A$ and glycine receptors (Krasowski and Harrison, 2000). It may also have effects at dopamine, serotonin, and opioid receptors due to its ethanol properties (Fish and Meyer, 2008).

Physiology

Tribromoethanol produces generalized CNS depression including the cardiovascular and respiratory centers. Duration of affect is species, strain, and route of administration dependant. Dogs and cats administered tribromoethanol rectally showed sedation for ~1 hour and 24 hours, respectively. Different strains of mice have significantly different dosing requirements (125 vs. 500 mg/kg IP) (Fish and Meyer, 2008).

It is undergoes hepatic conjugation and the glucuronide is excreted in the urine in rodents (Green et al., 1998). Tribromoethanol produces repeatable anesthesia, but sleep times can be variable in young or sick animals (Meyer and Fish, 2005).

Adverse Effects

Tribromoethanol is an irritant and produces inflammation and peritonitis when administered intraperitoneally, especially at high doses, high concentrations, or with repeated use (Meyer and Fish, 2005). Anesthesia with tribromoethanol can result in ileus, abdominal adhesions, increased generalized morbidity, as well as increased mortality (Meyer and Fish, 2005). It is recommended only for acute terminal studies when administered intraperitoneally (Fish and Meyer, 2008).

Tribromoethanol has been associated with impaired fertility (Meyer and Fish, 2005). Tribromoethanol degrades in the presence of heat or light to produce toxic byproducts. Degraded solutions can be both nephrotoxic and hepatotoxic. Administration of degraded tribromoethanol solutions has been associated with death, often 24 hours after surgery.

Dose

Due to the increased morbidity and mortality following anesthesia, and repeated anesthetics, tribromoethanol is recommended only for terminal studies (Fish and Meyer,

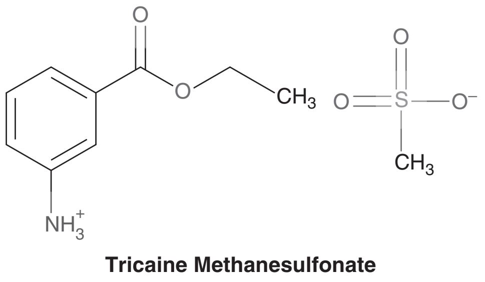

Figure 12.12 Tricaine methanesulfonate.

2008). The dose administered to mice is 150–500 mg/kg IP

Regulatory Information

Nonscheduled drug

Drug Availability

There are no FDA veterinary approved nor human approved products. When used, drug must be reconstituted from chemical powder.

Tricaine Methanesulfonate (MS-222)

History

Tricaine is the only anesthetic approved by the United States Food and Drug Administration for fish intended as food and in the USA is the most commonly used agent for the anesthesia of fish.

Chemistry

Tricaine (3-aminobenzoic acid ethyl ester methanesulfonate; Figure 12.12) is a white crystalline power that has a water solubility of 1.25 g/ml at 20°C. A stock solution of 10 g/l can be stored in an airtight container at room temperature. The solution should be stored in darkened containers as sunlight will cause the solution to turn brown. The addition of tricaine to water at relevant doses will cause the water to become acidic. At 100 mg/l the pH of the solution can be as low 5. It is therefore recommended to buffer the solution with sodium bicarbonate to a pH between 7.0 and 7.5.

Mechanism of Action

Tricaine produces generalized CNS depression but its direct mechanism of action is unknown. Tricaine is a water-soluble chemical structurally related to benzocaine, a local anesthetic. Local anesthetic drugs works by blocking conduction of sodium channels (see Chapter 15). It is reasonable to question if the lack of movement seen in fish anesthetized with tricaine is at least partially associated with blocked conduction of muscle as opposed to true CNS depression. There is evidence of impacts on nervous tissues as tricaine does decrease neural conduction in toadfish (Palmer and Mensinger, 2004). The structurally related drug, lidocaine, has also been shown to be analgesic and to function as a CNS depressant when given centrally in domestic mammals (Doherty and Frazier, 1998; Valverde et al., 2004). It is possible that tricaine may act similarly in fishes.

Physiology

Tricaine is rapidly absorbed via gill diffusion and provides a fairly rapid induction and recovery. The early stages can show some excitatory effects similar to those seen in terrestrial animals as they pass through an excitatory state (stage II anesthesia) before becoming immobile. Once immobile, tricaine is able to completely abolish muscle movement.

Physiological effects of tricaine include a decrease in heart rate, cardiac contractility, and dorsal aortic pressure (Hill et al., 2002). Anesthesia with tricaine also increased cortisol, glucose, hematocrit, and lactate (Cho and Heath, 2000).

Adverse Effects

Tricaine has a high therapeutic index and morbidity and mortality are rare, even with fish anesthetized for hours (Harms et al., 2005), provided physiological needs are met (e.g., water flow over gills).

Dose

The dose typically used in fish for anesthesia is 25–150 mg/l for induction of anesthesia, and 400–500 mg/l to produce euthanasia.

Regulatory Information

Controlled drug status: Nonscheduled drug.

Withdrawal information: Withdrawal time 21 days for fish harvested for food.

Drug Availability

FDA veterinary approved products:

Finquel, Argent Laboratories, powder for reconstitution
Tricaine-S, Western Chemical, Inc, powder for reconstitution

Human approved products: None

Opioid Analgesic Drugs

Butch KuKanich and Mark G. Papich

Introduction

The opioids include drugs that are true opiates – derivatives of opium – and drugs that are synthetic agents but also affect opiate receptors. Opiates include morphine, codeine, and thebaine isolated from the poppy plant. These drugs differ among one another primarily in potency, but also may have different pharmacokinetic and pharmacodynamic properties. Opioids include all the opiates, as well as synthetic drugs, such as fentanyl, methadone, and meperidine (pethidine) that are not chemically related to morphine but act as opiate receptor agonists. Various types of opiate receptors will be discussed later in the chapter.

The opioids are valuable tools in the veterinarian's armamentarium of drugs. Although most of the drugs in this group are controlled substances because of their potential for abuse by humans, they can have profound effects for treatment of animals (Table 13.1). There are many overlapping areas with other therapeutic uses discussed in other chapters of this book (for example Chapter 46 dealing with gastrointestinal drugs and Chapter 48 dealing with respiratory drugs – antitussives).

An important advantage of opioid analgesic drugs is their high efficacy and remarkable safety. If adverse effects are recognized, their short half-lives in animals usually produce a rapid alleviation of clinical signs. If adverse reactions are severe (e.g., dysphoria or life-threatening respiratory depression) these drugs also have the benefit of reversibility, which is accomplished quickly with administration of an opioid antagonist such as naloxone. This lack of serious adverse effects allows clinicians to gradually escalate doses of opioid agonists in patients as needed for pain or decrease dose if adverse effects occur in highly sensitive animals. Opioid agonists/antagonists may have a ceiling effect limiting the effectiveness of high doses, as discussed later.

Background on Opioids

Opioid Role in Analgesia

A nociceptive stimulus produces an unpleasant sensation. Pain is the coupling of the unpleasant sensation with conscious perception and eliciting an emotional response. There is debate on whether all animals have true emotional responses, and thus whether they can feel pain according to its definition, but there is no debate that nociception is present in animals. Nociceptive receptors are free nerve endings distributed throughout the body, which detect a nociceptive stimulus. Nociceptive stimuli are transmitted from peripheral nerves though the spinal cord to numerous areas within the central nervous system. Mechanical (pressure, fractures, stretching), temperature (hear or cold), and chemical (including endogenous substances such as inflammatory cytokines and changes in tissue pH) stimuli are all types of stimuli that produce pain. For the discussions in this chapter pain and nociception will be used synonymously.

Large strides have been made recently in the recognition and treatment of pain in animals. Numerous pharmacokinetic and pharmacodynamic studies have been performed in order to better gain our understanding of opioids in animals through laboratory and clinical studies. Treatment regimens used in humans cannot be easily extrapolated to animal species treated by veterinarians because of species differences in pain sensation, pharmacokinetic differences, efficacy, and adverse effects of opioids.

History of Opioids

Opioids are considered the prototypical analgesic, antidiarrheal, and antitussive drugs by which other drugs are compared. Opium was first imported into the

Increased locomotor activity (used illegally in performance horses for this purpose)

United States in 1840, primarily from the country of Turkey. It was widely used to treat a variety of maladies, including pain, diarrhea, and coughing. In the 1870s, because of widespread use after the Civil War, opiate use and addiction was a recognized problem. There are over 20 opiate alkaloids in opium and in the early 19th century, the chemist Sertürner isolated morphine, which he named after *Morpheus*, the Greek god of sleep and dreams. Heroin was also developed in the early 1900s by the same chemists at Bayer who developed aspirin. It was intended to be a safe and nonaddictive analgesic. There have been other attempts – none completely successful – during the next century to develop drugs as effective as the opiates, but without the abuse and addiction potential. The majority of opioids are now controlled by regulatory authorities.

In the United States, the Drug Enforcement Agency (DEA) and Food and Drug Administration (FDA) are the regulatory agencies. (Regulation of drugs is discussed in more detail in Chapter 55. Prescribing controlled drugs is discussed in Chapter 56.) The FDA approves drugs based on efficacy and safety, and drugs with the potential for abuse are scheduled by the DEA on the basis of its addictive potential (Schedule I through V). Schedule I (CI) drugs have no realistic medical benefit (e.g., heroin). Schedule II (CII) drugs can be highly addictive, but have important therapeutic uses. Morphine and most of the pure agonists are listed in Schedule II (Table 13.2). Schedule III (CIII) have an abuse potential, but less than CII drugs. Schedule IV (CIV) drugs have an abuse potential, but less than CIII drugs and Schedule V (CV) drugs have an abuse potential, but less than CIV drugs. Occasionally, a drug's schedule may change. For example, the DEA recently changed hydrocodone combination drugs (e.g., hydrocodone with acetaminophen) from CIII to CII drugs, and tramadol went from being an unscheduled drug to Schedule IV.

In veterinary medicine, the earliest recorded use of opium was in 1815, when it was considered important in the *Materia Medica* (Stalheim, 1990) (See Chapter 1 for a discussion of the *Materia Medica*.) In 1930, morphine was first recommended in a veterinary pharmacology textbook for treatment of horses for colic, cough, and analgesia. Although recommended for treatment of pain and colic in horses at that time, the adverse effects in horses were not recognized. Other drugs used in the early 20th century by veterinarians included combinations of morphine and atropine for pain in dogs and the use of paregoric (tincture of opium) for treatment of flatulence. Early veterinary preparations included paregoric, laudanum (opium), ipecac and opium (Diver's powder), morphine, heroin (0.5 to 2 grains for a horse), codeine, and dionin (ethylmorphine) (Stalheim, 1990).

Veterinary medicine has advanced considerably since those early years and it is common for modern veterinary hospitals to include morphine and other potent derivatives in their pharmacy. Injectable solutions for intermittent administration or constant rate infusion, oral formulations, and transdermal delivery devices are common in most veterinary hospitals used as preanesthetics, anesthetic adjuncts, and to provide analgesia among other uses.

Physiology of Opioids

Three main classes of opiate receptors have been identified: μ, κ, and δ (Table 13.3). Numerous opiate receptor subtypes have also been identified. In some textbooks, a sigma (σ) receptor is listed, but the significance of this receptor is not understood and is not considered a true opiate receptor by many pharmacologists.

Clinically, differences in mu (μ)-opioid effects have been observed in dogs with marked pharmacodynamic variability of effects. A morphine dose that produces desirable and predictable effects in most dogs may produce profound sedation in some individuals and marked dysphoria in others. In the past, these ranges of responses have been suggested to be "sensitivity" differences as the doses and plasma concentrations were within expected ranges. However, recent data suggest opioid receptor subtypes exist, which may contribute to the variability in opioid effects, but are not well characterized in dogs. Methadone combined with morphine and codeine produces a synergistic analgesic effect in mice, but only additive effects with other opioids such as oxymorphone and fentanyl, suggesting different receptor binding for morphine and methadone (Bolan et al., 2002). μ-opioid deficient mice (CXBX strain) are insensitive to morphine, but still respond to some other opioids including methadone and fentanyl, which also suggests μ-opioid subtypes exist (Vaught et al., 1988; Chang et al., 1998). Although only one μ-opioid receptor gene has been identified, multiple μ-opioid splice variants have been documented in rats, which may explain differential agonist effects (Verzillo et al., 2014). There have also been single nucleotide polymorphisms identified in the μ-opioid gene of dogs, which may play a role in opioid-induced dysphoria (Hawley and Wetmore, 2010).

Table 13.2 United States drug scheduling of the opioid narcotics; complete list may be found at: http://www.usdoj.gov/dea/pubs/scheduling.html. Source: United States Drug Enforcement Administration.

Substance	DEA number	Other names and brand names
Schedule I		
Acetyldihydrocodeine	9051	Acetylcodone
Benzylmorphine	9052	
Codeine methylbromide	9070	
Codeine-N-oxide	9053	
Desomorphine	9055	
Dihydromorphine	9145	
Etorphine (except HCl)	9056	
Heroin	9200	Diacetylmorphine, diamorphine
Morphine methylbromide	9305	
Morphine methylsulfonate	9306	
Morphine-N-oxide	9307	
Nicomorphine	9312	Vilan
Normorphine	9313	
Schedule II		
Alfentanil	9737	Alfenta
Carfentanil	9743	Wildnil
Dihydrocodeine	9120	Didrate, Parzone
Diphenoxylate	9170	
Diprenorphine	9058	M50-50
Ethylmorphine	9190	Dionin
Etorphine HCl	9059	M 99
Fentanyl	9801	Innovar, Sublimaze, Duragesic
Hydrocodone	9193	dihydrocodeinone
Hydrocodone and isoquinoline alkaloid 15 mg/du	9805	Dihydrocodeinone, papaverine or noscapine
Hydrocodone combination product 15 mg/du	9806	Tussionex, Tussend, Lortab, Vicodin, Hycodan, Anexsia
Hydromorphone	9150	Dilaudid, dihydromorphinone
Levomethorphan	9210	
Levorphanol	9220	Levo-Dromoran
Meperidine	9230	Demerol, Mepergan, pethidine
Methadone	9250	Dolophine, Methadose, Amidone
Methadone intermediate	9254	Methadone precursor
Morphine	9300	MS Contin, Roxanol, Duramorph, RMS, MSIR
Opium extracts	9610	
Opium fluid extract	9620	
Opium poppy	9650	Papaver somniferum
Opium tincture	9630	Laudanum
Opium, granulated	9640	Granulated opium
Opium, powdered	9639	Powdered Opium
Opium, raw	9600	Raw opium, gum opium
Oxycodone	9143	OxyContin, Percocet, Tylox, Roxicodone, Roxicet,
Oxymorphone	9652	Numorphan
Racemethorphan	9732	
Racemorphan	9733	Dromoran
Remifentanil	9739	Ultiva
Sufentanil	9740	Sufenta
Schedule III		
Buprenorphine	9064	Buprenex, Temgesic
Butabarbital	2100	Butisol, Butibel
Codeine combination product 90 mg/du	9804	Empirin, Fiorinal, Tylenol, ASA or APAP w/codeine
Nalorphine	9400	Nalline
Schedule IV		
Butorphanol	9720	Stadol, Stadol NS, Torbugesic, Torbutrol
Pentazocine	9709	Talwin, Talwin NX, Talacen, Talwin Compound
Schedule V		
Codeine preparations: 200 mg/100 ml or 100 g		Cosanyl, Robitussin A-C, Cheracol, Cerose, Pediacof
Dihydrocodeine preparations: 10 mg/100 ml or 100 g		Cophene-S, various others
Diphenoxylate preparations: 2.5 mg/25 μg atropine sulfate		Lomotil, Logen
Ethylmorphine preparations: 100 mg/100 ml or 100 g		
Opium preparations: 100 mg/100 ml or 100 g		Parepectolin, Kapectolin PG, Kaolin Pectin P.G.

Table 13.3 Opiate receptor types and their associated effects (some textbooks also list the sigma-receptor, but this may not have any significance)

μ Receptor	κ Receptor	δ Receptor
Analgesia (spinal and supraspinal)	Analgesia (spinal and supraspinal)	Analgesia (spinal and supraspinal)
Respiratory depression		
Decrease gastrointestinal motility	Decrease gastrointestinal motility	
Decrease gastrointestinal secretions	Decrease gastrointestinal secretions	
Decrease biliary secretions		
Increase appetite	Increase appetite	Increase appetite
Sedation/excitement (dose and species dependent)	Sedation	
Euphoria		
Antidiuresis	Diuresis (decrease ADH release)	
Decrease urine voiding reflex		
Decrease uterine contractions		
Miosis/mydriasis (species specific)	Miosis/mydriasis (species specific)	
Nausea/vomiting or antiemetic (drug specific)	Nausea/vomiting or antiemetic (drug specific)	
Immunomodulation		Immunomodulation

ADH, antidiuretic hormone.

Endogenous opioids are natural chemicals in the body (peptides) that interact with opiate receptors to produce natural physiological responses, including modulation of pain. β-endorphin is the endogenous opioid peptide with the highest affinity for μ receptors and is derived from proopiomelanocortin. Leucine- and methinone-enkephalin are derived from proenkephalin and are the endogenous ligands for the δ receptor. Dynorphin A is the endogenous ligand for the κ receptor and is derived from prodynorphin. The role of dynorphins remains controversial because they induce sensitization of nociceptive transmission through activation of NMDA receptors.

An endogenous opioid peptide, termed nociceptin or orphanin FQ (N/OFQ), with similar homology to dynorphin, has also been described (Meunier et al., 1995; Reinscheid et al., 1995). Orphanin precursors have been identified in the hippocampus, cortex, and numerous sensory sites (Neal et al., 1999). Exogenous N/OFQ administration results in a variety of responses ranging from analgesia to antianalgesia and opioid antagonism. However, N/OFQ antagonists have consistent analgesic properties when administered supraspinally, which may prove to be a useful target for analgesics in the future (Heinricher, 2005). However, no drugs affecting N/OFQ receptors are currently available for use, therefore these drug classes will not be addressed in this chapter.

Opioids have been characterized by the type of interaction with the opiate receptor type(s) with which they interact (μ, κ, and δ), and by the effect elicited upon binding (Figure 13.1). Opioids may be full agonists, partial agonists, antagonists, and combinations thereof. An agonist produces a dose-dependent effect which eventually plateaus with unconsciousness. A partial agonist binds to the opiate receptor, but plateaus at a sub-maximum response (less than a full agonist) despite

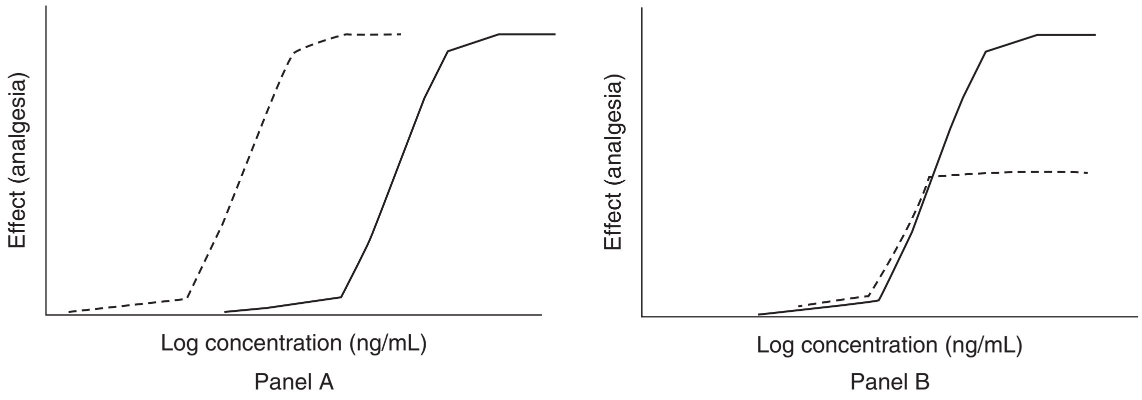

Figure 13.1 Panel A demonstrates two drugs with equal efficacy, but different potency such as fentanyl and morphine. Panel B demonstrates drugs with equal potency, but different efficacy such as fentanyl and buprenorphine.

increasing doses. The opioid antagonists are competitive antagonists which bind to the receptor but do not result in receptor activation and may displace the agonist from the opiate receptor in some cases, resulting in "reversal" of effects. Morphine is a full agonist at the μ receptor whereas buprenorphine is a partial agonist. Nalbuphine is an antagonist at the μ receptor but an agonist κ at the receptor. Naloxone is primarily an antagonist at the μ receptor but also has antagonist effects at the κ and δ receptors.

Opioid Pharmacodynamics

Analgesia

Opioids exert their primary analgesic effect by binding to spinal and supraspinal receptors (Tables 13.3 and 13.4). However, peripheral effects of opioids have been documented by local injection of opioids in joints (intraarticular injection) at doses that do not produce systemic effects and the effect is abolished when injected with naloxone (Stein et al., 1991).

When an opioid binds to spinal receptors it produces activation of G-coupled proteins (which inhibit adenylyl cyclase), activation of receptor linked K^+ ion channels, and inhibition of voltage gated Ca^{2+} channels. Presynaptic μ, κ, and δ spinal receptors are present in the dorsal horn of the spinal cord, decreasing excitatory neurotransmitter release by decreasing the rate of calcium influx. Postsynaptic μ receptors are also present in the dorsal root ganglion, which hyperpolarize the neuron by increasing potassium channel conductance resulting in a decreased propagation of the nociceptive signal.

The supraspinal opioid pathways are poorly understood, but concurrent activation with spinal receptors result in analgesic synergism (Roerig and Fujimoto, 1989; Yeung and Rudy, 1980). Synergism also exists between supraspinal μ and δ receptors when concurrently activated. Microinjection of morphine into the periqueductal gray (PAG) region results in inhibition of γ-amino butyric acid (GABA) interneurons, resulting in activation medullary pain inhibitory pathways (descending pathways) that inhibit dorsal horn nociceptors through release of serotonin (Yaksh and Tyce, 1979). Subsequent studies identified norepinephrine contributing a greater inhibitory effect than serotonin using knockout mice (Hall et al., 2011).

Full μ-opioids can provide a more profound analgesic effect than partial μ-agonists or κ-agonists for acute pain. However, partial μ-agonists and κ-agonist can still be effectively used for mild to moderate pain conditions if appropriate doses and dose intervals are chosen. The partial agonists or agonists/antagonists may be preferred in

animals that exhibit excitement or dysphoria caused by a pure μ-agonist.

Analgesia from systemic opioids are primarily limited to effects on c fiber nociceptors (slow conduction, unmyelinated nociceptors that transmit poorly localized, dull aching pain) when administered at clinical dosages. The Aδ nociceptors (fast conduction, myelinated nociceptors that transmit sharp localized pain) are minimally affected by systemic doses of opioids, which is the reason systemic opioids alone are inappropriate for invasive surgical procedures and anesthesia is required. Epidural opioids may produce high concentrations at the spinal level, which may inhibit both c-fiber and Aδ fiber nociceptors, producing greater analgesia but alone are insufficient for invasive surgical procedures. In contrast, epidural local anesthetics will completely block spinal nerve (and pain) transmission caudal to the injection site and some surgical procedures could be humanely performed.

The evaluation of analgesic response to opioids in animals is limited by other properties of the drugs (e.g., sedation) or misinterpretation of response because of dysphoria, panting, or ataxia. Innate behaviors of animals also often confound our ability to interpret responses to opioids. Clinical assessments include subjective measures that may not be indicative of pain. Placebo rates for postoperative pain studies in dogs undergoing soft tissue and orthopedic surgery have been as high as 100%. The extrapolation of experimental models of antinociceptive responses to clinical effects of these drugs is not straightforward and may overestimate or underestimate the degree and duration of analgesia. Nevertheless, many of the dosing regimens discussed in this chapter are made using information obtained from experimental models and clinical trials in the species of interest in addition to extrapolation from other species including humans.

Respiratory Depression

Opioids produce a dose-dependent respiratory depression mediated via activation of the μ receptor. Respiratory depression is produced by a decreased response to increases in carbon dioxide partial pressures ($P\text{CO}_2$). The respiratory depressant effects of opioids are well tolerated in healthy animals even when supratherapeutic doses are administered. Concurrent anesthesia or other drugs that cause respiratory depression can increase the respiratory depressant effects of opioids (Hug et al., 1981). Respiratory depressant effects may be more problematic in animals with preexisting respiratory disease (asthma, bronchitis, cor pulmonale) or increased intracranial pressure. Neonatal animals (young, healthy, and pain free) tend to be more sensitive to the respiratory depressant effects of opioids, but opioids can still be safely administered to neonates.

Opioids cross the placenta and respiratory depressant and sedative effects on the fetus can occur and should be monitored and treated appropriately. Naloxone administered sublingual (or parenterally) to newborns will reverse deleterious opioid effects.

Central Nervous System Excitation

High doses of morphine and other opioids produce excitement. Very high doses can produce convulsions. Similarly, rapid IV administration of opioids can cause CNS excitation. In dogs, morphine, 180–200 mg/kg IV, produced grand mal seizures, and convulsive changes in electroencephalogram (EEG) tracings and excitement were seen in dogs administered morphine 20 mg/kg SC (Wikler and Altschul, 1950; de Castro et al., 1979). (Note that therapeutic doses rarely exceed 0.5–1 mg/kg.) Cats respond similarly to high doses of morphine where 20 mg/kg SC produced EEG tracings consistent with convulsive activity and generalized excitement (Tuttle and Elliot, 1969).

In veterinary medicine, there are great species differences with respect to excitement caused by opioids. Dogs typically become sedate, whereas cats, horses, and other large animal species are prone to excitement. The explanation for increased susceptibility to these effects in some animals is probably related to the distribution of opiate receptors in certain regions of the brain independent of the drug's pharmacokinetics. The distribution of opiate receptors in brains of animals that are sedated from opioids (e.g., dogs) is greater than the animals that are more prone to excitement (horses). Alternatively, the excitement may be due to a release of excitatory neurotransmitters or decreased release of inhibitory neurotransmitters. Some anesthesiologists suggest that the reaction may be dopaminergic, adrenergic, or caused by decreased activity of the inhibitory neurotransmitters GABA or glycine (Werz and Macdonald, 1982). Release of acetylcholine also has been suggested as a cause of excitation (Mullin et al., 1973). In another study, it was suggested that excitement in animals may be caused by histamine release, but the doses of morphine exceeded clinically recommended doses in those studies. Morphine administration to dogs induced greater histamine release, and also more excitement compared to oxymorphone after administration of an equianalgesic dose, but the doses of morphine (2 mg/kg IV) were four times higher than recommended clinically (Robinson et al., 1988). When morphine was compared to hydromorphone in dogs (Guedes et al., 2007a), morphine caused a transient increase in plasma histamine and 1/5 dogs also exhibited neuroexcitatory behavior at 0.5 mg/kg IV. By contrast, hydromorphone did not cause increases in histamine but two dogs became excited after 0.1 mg/kg IV. These studies indicate

Table 13.5 Pharmacokinetic parameter of opioids administered IV and PO bioavailability in dogs and cats

histamine alone is not a cause of opioid-induced CNS excitation.

Cats are one of the species that is more sensitive to morphine-induced CNS excitation and dysphoria. There are isolated studies in which cats have tolerated morphine doses up to 2 mg/kg (Barr et al., 2000), but lower clinical doses are generally administered to cats compared to dogs. The differences between dogs and cats are not attributed to pharmacokinetics. Although cats have somewhat lower clearance for some opiates (Table 13.5), this difference is not enough to account for opioid-induced excitement in cats.

Horses are also more sensitive to the excitement caused by this group of drugs. Because of this, pure opioid agonists such as fentanyl and morphine are not recommended to be used alone. Dose-dependent excitation and increased locomotor activity has been observed in horses and may occur before maximum analgesia is obtained with the degree of excitation dependent on the specific opioid, individual variability, and degree (or lack thereof) pain in the horses (Muir et al., 1978; Tobin et al., 1979; Mama et al., 1992). For example buprenorphine, normally well tolerated in dogs and cats, produced restlessness, excitement, head shaking, pawing, and leg shifting at a dose of 5 and 10 μg/kg IV in healthy pain-free animals that was dose dependent (Carregaro et al., 2006, 2007; Messenger et al., 2011; Davis et al., 2012). However, administration of 10 μg/kg IV in separate studies did not produce excitement, but increased locomotor activity was still observed in healthy pain-free horses (Love et al., 2015). Buprenorphine, 10 μg/kg administered as part of a preanesthetic protocol for castration, was well tolerated with no excitement, but increased locomotor activity occurred (Love et al., 2013). Morphine was investigated for its use as an anesthetic adjunct for healthy pain-free horses at doses of 0.25 and 2 mg/kg IV with isoflurane anesthesia (Steffey et al., 2003). The authors concluded that undesirable and dangerous behavior during recovery from 2 mg/kg IV morphine still persisted after 4 hours, and did not support the use of high doses of morphine as an anesthetic adjunct in this regimen. However, the recovery and effects of 0.25 mg/kg morphine were similar to the saline-treated group. When opioids have been used in painful horses, fewer adverse reactions are observed (Mircica et al., 2003; Devine et al., 2013). Only 1 of 75 clinically treated horses administered morphine (0.1 mg/kg IM) had excitation reported and it was unclear if it was drug related or simply caused by the behavior of an untrained animal (Devine et al., 2013).

Cardiovascular Effects

Most opioids have minimal effects on cardiac output in dogs, with clinically relevant doses resulting in changes ranging from slight increases to slight decreases, but methadone may produce more consistent decreases in cardiac output (Buckhold et al., 1977; Priano and Vatner, 1981; Copland et al., 1987; Maiante et al., 2009). Opioids produce bradycardia in dogs, but they usually compensate well to maintain cardiac output and treatment for the bradycardia is not routinely needed (Copland et al., 1992). Only if necessary should bradycardia can be reversed with an anticholinergic (e.g., atropine). Cardiac output is also maintained with opioids in horses and may be increased if excitatory effects occur (Muir et al., 1978; Robertson et al., 1981; Carregaro et al., 2006).

Opioids produce minimal vascular effects when administered to animals in clinically relevant doses (Barnhart et al., 2000; Pant et al., 1983; Hug et al., 1981; Kayaalp and Kaymakcalan, 1966; Priano and Vatner, 1981; Carregaro et al., 2006). Changes in mean arterial pressure range from minimal increases to minimal decreases (~10% from baseline values). Increases in plasma histamine concentrations following morphine administration are often cited as producing hypotensive effects in dogs, but histamine release is short lived (Guedes et al., 2007a) and minimal effects on blood pressure are noted following IV morphine administration. The cardiovascular effects of opioids appear to be more pronounced in anesthetized animals due to interactions with the anesthetic and when supratherapeutic opioid are administered.

The effects of opioids on myocardial blood flow are variable with some studies demonstrating increases in blood flow where others show decreases, but these studies assessed supratherapeutic doses, ≥2 mg/kg (Pant et al., 1983; Vatner et al., 1975). This is in contrast to the consistent effects in humans, coronary vasodilation and increased myocardial perfusion.

Morphine's effect on vascular tone has been used in the past as a treatment for acute cardiogenic pulmonary edema (Vismara et al., 1976). The benefits are attributed to splanchnic blood pooling, afterload reduction, or reduced breathing effort. Some investigators attributed the benefits to vasodilation caused by histamine release. This is considered a rather outdated use of morphine. Today we have potent diuretics and vasodilators to treat this condition.

Antitussive Effect

Opioids produce an antitussive effect through a central inhibition of the cough center independent of their respiratory depressant effects (Chou and Wang, 1975). Both μ- and κ- receptor agonists have been documented to produce antitussive effects (Takahama and Shirasaki, 2007). The antitussive effect is more resistant to naloxone reversal than the analgesic effect of opioids (Chau et al., 1983). Morphine, codeine, butorphanol, and methadone have demonstrated antitussive effects in dogs or cats, and tramadol additionally in cats (Rosiere et al., 1956; Cavanagh et al., 1976; Nosal'ova et al., 1991). Hydrocodone has antitussive properties in rats and people, and is commonly used in dogs for this purpose although studies definitively demonstrating its efficacy in dogs and cats are lacking (Kasé et al., 1959; Hennies et al., 1988; Homsi et al., 2002).

Dextromethorphan, which does not affect opiate receptors, is used as an over-the-counter medication to treat coughing in people. It is believed to bind to high- and low-affinity sites in the brain that are distinct from opiate receptors (Grattan et al., 1995). A steric hindrance may prevent binding to the typical opiate receptors responsible for analgesic and other effects. In people, it is more effective in spontaneous naturally occurring cough than in experimental models (Capon et al., 1996). Dextromethorphan has been shown to be an effective antitussive in dogs after IV injection (ED_{50} = 10.2 mg/kg IV), but the oral bioavailability is questionable (discussed more specifically later in Section Clinical Pharmacology, Antitussive) (Kasé et al., 1959; KuKanich and Papich, 2004a). Because it is believed that the parent drug, dextromethorphan, rather than a metabolite, is responsible for the antitussive effect (Capon et al., 1996), it is unlikely that oral administration will be effective as an antitussive in dogs.

Gastrointestinal Effects

Emetic Properties

Emesis and nausea can occur following administration of opioids via stimulation of the chemoreceptor trigger zone (CRTZ) (Mitchelson, 1992). Opioids also may stimulate central dopamine (D_2) receptors in the vomiting center to produce vomiting. Opioids appear to have differing emetic effects, with morphine causing emesis more frequently than hydromorphone or oxymorphone in dogs (Valverde et al., 2004). The emetic response is complicated by the observation that opiates also act as antiemetics in the vomiting center (Scherkl et al., 1990), with an antiemetic effect predominant for butorphanol, methadone, and fentanyl (Schurig et al., 1982; Blancquaert et al., 1986). It is not unusual to observe emesis after an initial dose of morphine or hydromorphone to a patient, but not with subsequent doses. Apomorphine administered initially will produce reliable emesis in dogs, subsequent doses do not (Khan et al., 2012). Apomorphine is discussed in more detail in Section Opioid Agonists, Apomorphine. It is commonly observed that vomiting occurs after morphine administration to pain-free animals (e.g., premedication, research animals), but vomiting is not commonly observed in animals with moderate to severe pain (e.g., trauma). These observations may be related to the antiemetic effects produced after an initial dose, the antiemetic effects produced by endogenous opioids in painful patients, or mitigation of emesis by pain.

Since the CRTZ is not protected by the blood–brain barrier, low plasma concentrations can produce emesis following oral morphine administration without producing an analgesic effect (Blancquaert et al., 1986; KuKanich et al., 2005a). In cats, morphine appears to produce more of an emetic effect as compared to fentanyl, meperidine, buprenorphine, and butorphanol (Taylor et al., 2001;

Robertson et al., 2003; Robertson et al., 2005). Hydromorphone produces signs of nausea (salivation and lip licking) in cats and may elicit emesis (Wegner et al., 2004).

Release of histamine or dopaminergic effects also may produce emesis. Apomorphine, one of the most reliable emetics in dogs, is a central-acting dopamine (DA_1, DA_2) agonist. Dopamine is one of the neurotransmitters in the vomiting center as well as in the CRTZ. Likewise, histamine is released for a short time after morphine administration to dogs (Guedes et al., 2007a) and histamine is also known as one of the neurotransmitters involved in emesis.

Gastrointestinal Motility

Opioids produce a decrease in gastrointestinal motility via both central and peripheral mechanisms. Opioid-mediated effects in the gastrointestinal tract are through the μ, κ, and δ opiate receptors. The review by DeHaven-Hudkins et al. (2008) provided details on the distribution of the receptors in the gastrointestinal tract and effects associated with stimulation, either from endogenous opioids or exogenous opioids. Opioid receptor-mediated stimulation of the gastrointestinal tract slows gastric emptying, decreases fluid secretion and increases intestinal fluid absorption, reduces propulsive motility, and increases pyloric and other sphincter tone. Expression of μ opiate receptors have been found in the submucosal plexus, myenteric plexus, and longitudinal muscle of the ileum. In healthy animals, the regulation of these receptors and their function helps to maintain gut homeostasis within the enteric nervous system by coordinating intestinal motility and intestinal secretions. Motility-induced changes by the μ, κ, and δ opiate receptors are accomplished by inhibiting Ca^{2+} channels decreasing the release of intestinal acetylcholine (Ach) and/or substance P (Cherubini et al., 1985; Galligan and Akbarali, 2014). The μ and δ opiate receptors also result in membrane hyperpolarization and decreased cAMP and protein kinase A (PKA) activity, resulting in reduced neuronal excitability. The μ and δ opiate receptors decrease intestinal fluid secretion by inhibition of chloride secretion and passive water movement into the colon. The clinical consequence is constipation or antidiarrheal effects.

After the initial emetic effect, opioids decrease gastric motility, resulting in prolonged gastric emptying. Opioids can also increase the tone of the antrum and the duodenum resulting in difficult intubation with an endoscope. The small intestinal effects of opioids initially appeared to be limited to the proximal portions; however, additional studies demonstrated effects on the ileum as well. Decreased propulsive motility and decreased intestinal, pancreatic, and biliary secretions occur in the small intestine. There is increased tone of all gastrointestinal sphincters, including those of the pancreatic duct. However, increases in rhythmic, segmental, nonpropulsive contractions also occur, which enhances reabsorption of water.

Morphine initially stimulates large bowel motility and defecation often occurs shortly after administration in dogs and cats (Tuttle and Elliot, 1969; Barnhart et al., 2000; Lucas et al., 2001). Following initial defecation, opioids produce a decrease in colonic propulsive motility and secretions, but increases in nonpropulsive rhythmic contractions occur similar to that in the small intestine. Therefore the passage of colonic contents is delayed and the fluid content is decreased. The decreased gastrointestinal motility can result in constipation, an adverse effect, or can be used therapeutically as a treatment for diarrhea.

The decrease in intestinal motility is profoundly important for horses. Horses treated for pain are often prone to ileus. Administration of opioids to horses will decrease production of feces, decrease intestinal sounds, and potentially lead to ileus and constipation (Boscan et al., 2006). The effects are best known for morphine, but also can occur with butorphanol, an agonist/antagonist (Sellon et al., 2001). The butorphanol effects are dependent on method of administration because when butorphanol was administered by a constant rate infusion, the intestinal effects were less compared to an IV bolus injection (Sellon et al., 2001).

Urinary Tract

Opioids produce a variety of effects on the urinary tract. μ-agonists increase the tone of urinary sphincters. Micturition is inhibited, which may result in urine retention and may be mediated by spinal as opposed to local mechanisms (Drenger et al., 1986, 1989).

Mu-receptor agonists decrease urine production. As discussed by Robertson et al. (2001), although it has been documented that morphine produces an antidiuretic effect and decrease in urine output, the exact mechanism is unclear. It is not known whether it is caused by a release of arginine vasopressin (AVP) (also known as antidiuretic hormone), or via some other mechanism. In contrast, κ opioid agonists produce a diuretic effect as a result of decreased AVP concentrations (Craft et al., 2000). For a drug such as morphine that acts as an agonist for both receptors, the net effect observed clinically is diuresis in most situations. This is complicated by the effect on the urinary bladder. Morphine increases the tone of the sphincter of the urinary bladder, making it more difficult for some animals to voluntarily urinate. Morphine also inhibits the urinary voiding reflex. As a result of these effects hospitalized animals should be monitored and interventions used to facilitate bladder emptying when necessary.

Immune System Effects

The effects of opioids on the immune system are complex. The immune system effects are likely related to the specific opioid administered, dose, and the duration of treatment. A complex interaction of the immune system, sympathetic nervous system, endocrine system (hypothalamic–pituitary–adrenal axis), and direct effects on leukocytes occur. Immunosuppressive and immuostimulant properties have been identified depending on the experimental conditions. Some painful patients may benefit from opiate effects on immune function (Page and Ben-Eliyahu, 1997). Extrapolations of the effects of opioids on the immune system from studies on human opioid abusers are likely inaccurate for veterinary patients because studies in humans are in the context of high dose administration, chronic use, and tolerance of human opioid abusers.

Tolerance and Dependence

Although these traits are often associated with opioid use in humans, they have been well documented in animals. Tolerance and dependence can be demonstrated in animals, but opioids are seldom used for a long-enough period of time at large-enough dosages in veterinary patients for this issue to have clinical consequences. The NMDA receptor may play a role in opioid tolerance and dependence as treatment with NMDA antagonists attenuate withdrawal symptoms in experimental settings (Yeh et al., 2002). The consequence of tolerance is that drug dosages may need to be increased with chronic administration of opioids.

Opioids administered for a period as short as 5–7 days may result in dependence in dogs. In one study in dogs, constant rate infusion to dogs at a rate of 1–5 mg/kg/day produced physical dependence by day 8 (Yoshimura et al., 1993). Withdrawal signs can be elicited in dogs after dependence with injections of naloxone. Signs of withdrawal in dogs include nausea, aggression, vocalization, vomiting, hyperactivity, hyperthermia, tremors, and salivation. Withdrawal can also be elicited from administration of a μ antagonist or partial agonist such as butorphanol or buprenorphine in opioid-dependent dogs (Yoshimura et al., 1993).

Therefore, if an animal has been receiving continuous opioids drugs for longer than 5–7 days, withdrawal signs may occur after administration of an antagonist or partial agonist. However, clinical experience suggests that discontinuing the opioid rarely causes withdrawal signs for durations of administration less than a week. In contrast, withdrawal signs have occurred clinically when butorphanol (μ-antagonist) was administered to a dog after 1 week of morphine administration. Decreasing the dose of the μ agonist to wean a patient off an opioid or decrease opioid effects is a better strategy than switching to a partial agonist or antagonist.

Table 13.6 Chemical properties of opioids

Opiate	LogP[a]	Solubility (mg/l)	pKa
Meperidine	2.72	6550	8.59
Buprenorphine	4.98	0.0168	8.31

Morphine	0.89	149	8.21

[a] LogP, log of the octanol/water partition coefficient.

Opioid Pharmacokinetics

Opioids tend to be well absorbed when administered orally, intramuscularly, or subcutaneously. However, because of substantial first-pass metabolism the oral administration of most opioids results in poor bioavailability and erratic plasma concentrations in animals. Administration of opioids per rectum to animals result in a minimal increase in bioavailability over oral administration, since the majority of drug absorbed by this route of administration is still subject to first-pass hepatic metabolism due to uptake into the portal vein. Nasal and oral transmucosal administration of opioids can bypass first-pass hepatic metabolism. However irritation, the volume of drug to be delivered, dosing frequency, and species specific differences have limited the clinical effectiveness of transmucosal administration to buprenorphine in cats.

Opioids are well distributed throughout the body. Opioids are bound to plasma proteins in variable amounts from low to high protein binding depending on the individual drug. The opioids are lipophilic and weak bases. A comparison of the lipophilicity, designated by the octanol/water partition coefficient, is shown in Table 13.6. The higher the partition coefficient, the greater is the lipophilicity. All are weak bases (some have acidic groups also) with pKa values above 8. This indicates that lipophilicity increases at pH values of 8 and higher. These physiochemical properties favor intracellular accumulation. Consequently, opioids have a large volume of distribution, which greatly exceeds total body water. Additionally, administration of opioids with high lipophilicity, such as fentanyl (the highest Log P in Table 13.6), can produce rapid redistribution from tissues that are highly perfused, such as the central nervous system, to tissues that are less perfused, such as muscle and fat. The result is a more rapid decrease in concentrations (and effect) in the target organs in comparison to total body elimination. Repeated doses or a constant rate infusion may result in drug accumulation with an increased effect and slower than expected recovery. This phenomenon is similar to that seen with repeated doses of thiobarbiturates.

Systemic clearance of most opioids in animals is high. As seen in Table 13.5, clearance approaches or exceeds hepatic blood flow for most drugs, designating these as *high clearance* drugs. Most opioids are metabolized to more polar compounds and subsequently excreted in the urine or bile, but a small amount of unchanged drug may be eliminated in the urine and feces. Conjugation reactions are the primary means for some opioid metabolism (e.g., morphine and codeine), although cytochrome P450 (CYP) mediated metabolism can also occur (e.g., fentanyl, methadone), which are compound and species specific. Some of the conjugated products (e.g., glucuronide conjugates of opiates) are pharmacologically active, but because of their higher polarity may not cross the blood–brain barrier. Extrahepatic metabolism of morphine occurs in dogs, resulting in clearance rates exceeding the combined hepatic blood flow and glomerular filtration rates. Glucuronide conjugation is the primary conjugation pathway of morphine in most animal species except cats, which are a species deficient in some glucuronidation mechanisms (Court and Greenblatt, 1997). Sulfate conjugation is the primary means of morphine metabolism in cats. Despite differences in metabolic pathways, cats effectively metabolize morphine with total body clearance approximating the expected hepatic blood flow rate indicative of a high extraction drug (Table 13.5). Oxidative metabolism, mediated by CYP, appears to be the primary mechanism of fentanyl (and derivatives), methadone, and meperidine metabolism. Remifentanil is metabolized by tissue and plasma esterases and produces an extremely short half-life. The pharmacokinetic parameters of opioids in dogs and cats are presented in Table 13.5.

Clinical Pharmacology

Analgesia

Opioids are commonly used for analgesia and to relieve pain and anxiety from painful syndromes. Clinically, it is observed that there is great variability in response among patients, and between drugs. High variability has been recorded for pharmacokinetics in a species and analgesic responses varied by many fold in experimental studies. Therefore, careful observation and a willingness to adjust doses (or switch drugs) in individual patients is important to successful pain management.

Severe pain, often associated with trauma, should be treated with μ opioids agonists with high intrinsic activity (e.g., morphine, hydromorphone, fentanyl, methadone). Although some references have stated opioids should not be administered to painful animals in shock, there is no basis for this recommendation. Pain can contribute markedly to the adverse and life-threatening effects associated with shock and opioids often improve the hemodynamics and tissue perfusion of painful patients. As previously stated, the hypotensive effects of intravenous opioids (including morphine) are minimal when administered in clinically relevant doses, and concurrent supportive measures, such as fluid therapy, are essential to successful therapy in these patients. Mild to moderate pain (e.g., soft tissue surgery) has been managed with μ opioid agonists, partial agonists, mixed agonist–antagonists, or tramadol. The efficacy (and lack thereof) and variability of oral tramadol are discussed later.

Preemptive analgesia, dose administration prior surgical or a painful stimulus and continued into the postoperative period, provides more effective analgesia than holding off administration of opioids to the postoperative period in dogs (Lascelles et al., 1997). This is thought to occur by decreasing central sensitization (also known as the wind-up phenomenon).

Chronic and neuropathic pain appear to be less responsive to opioid analgesia. Higher doses of opioids in humans are needed for controlling neuropathic pain (Rowbotham et al., 2003). For neuropathic pain, it may be more effective to use a multimodal approach utilizing opioids in combination with other drug classes such as NMDA antagonists (e.g., ketamine), gabapentin, local anesthetics (e.g., lidocaine), or α-2 agonists (e.g., dexmedetomidine) appear to be more effective in refractory cases.

Antitussive

Butorphanol tablets (Torbutrol) are approved by the FDA for antitussive use in dogs. Hydrocodone is also routinely prescribed for its antitussive effects in dogs (see Chapter 48). Codeine exhibits poor bioavailability in dogs and may not be effective when administered orally. (Codeine has questionable antitussive properties in people as well (Takahama and Shirasaki, 2007).) Tramadol tablets have demonstrated effectiveness as an antitussive in experimental models in cats due to the formation of an opioid metabolite, but have yet to be evaluated clinically. All opioid agonists are expected to be effective antitussives when administered parenterally. As mentioned previously, oral dextromethorphan – a nonopiate that is a common ingredient in human over-the-counter cough medications – is probably not an effective antitussive in dogs because of the low oral bioavailability and lack of activity from metabolites.

Congestive Heart Failure

As mentioned Section Opioid Pharmacodynamics, Cardiovascular Effects, routine use of morphine is no longer recommended in treatment of congestive heart failure in animals due to variable effects on coronary blood flow. Likewise, although used in the past as a treatment for acute cardiogenic pulmonary edema (Vismara et al., 1976), this is no longer a common use.

Antidiarrheal

Opioids are effective antidiarrheal drugs as they decrease gastrointestinal secretions, decrease propulsive gastrointestinal contractions, and increase nonpropulsive segmental gastrointestinal contractions (see Chapter 46). Loperamide is the most commonly recommended opioid for the treatment of diarrhea because of reliable effects, availability over the counter (not a controlled substance), low cost, and safety profile. Loperamide is p-glycoprotein (p-gp) substrate and as a result is excluded from the CNS in normal animals. However, if concurrent p-gp inhibitors (e.g., cyclosporine, ketoconazole, spinosad) are coadministered or the animal is deficient in p-gp (some Collie dogs, Collie related breeds, and other herding breeds) than sedation, dysphoria, and other marked CNS opioid effects may be noted for prolonged periods of time, which may exceed 24 hours (Hugnet et al., 1996). Diphenoxylate in combination with atropine is also marketed as an antidiarrheal for humans, but is not used frequently in veterinary medicine as it has not demonstrated increased efficacy over loperamide. Diphenoxylate is a prescription drug, and is a schedule V controlled substance requiring special record keeping.

Sedation Anesthesia

Opioids are commonly coadministered with sedatives, tranquilizers, and anesthetics. Additive or synergistic sedative and analgesic effects occur when opioids are used in combination with sedatives and anesthetics. Combinations of these drug classes result in decreased dosages of the individual drugs with the potential for decreased adverse effects. Additionally, preemptive analgesia increases the effectiveness of postoperative analgesics, decreasing opioid consumption, adverse effects, and cost. A more thorough review of sedation and anesthesia drug combinations is presented in Chapters 12 and 14.

Contraindications, Warnings, and Drug Interactions

Head Trauma

As a drug class opioids exhibit a wide safety margin. Cautious use of opioids in patients with head trauma is warranted as respiratory depression may increase blood carbon dioxide concentrations resulting in cerebral vasodilation and worsening effects of cerebral edema. However, use of lower doses more frequently or constant rate infusions will mitigate some of the adverse effects as they are concentration (peak) proportional.

Temperature Regulation

Opioids have varying effects on temperature regulation depending on the species (Adler et al., 1988). Panting occurs after administration of some opioids in some dogs. Hydromorphone and oxymorphone caused 60% of the dogs to pant in one study (Smith et al., 2001). Panting can be aggravating, especially in animals being induced with inhalant anesthetics or undergoing diagnostic procedures such as radiography or ultrasound, but is usually self-limiting. It is not related to effects on the respiratory center, but is a reaction to the effect of opioids on the thermoregulatory center of the hypothalamus, whereby the body's set point is typically decreased by 1–3°F and dogs pant to lower their temperature. The depression of a dog's body temperature is a consistent finding in published studies (Lucas et al., 2001).

In contrast, administration of opioids has produced increase in body temperature in cats, horses, cattle, swine, and goats. Hydromorphone has been the best documented to produce this reaction, but other opioids are also associated with hyperthermia including morphine, buprenorphine, and butorphanol (Posner et al., 2007; Niedfeldt and Robertson, 2006). In published studies hyperthermia associated with hydromorphone has been as high as 41–42°C (107–108°F) in cats, for as long as 5 hours. The authors of these studies warn of high temperatures affecting postoperative recovery in cats when opioids are used for analgesia or perioperative sedation.

Interactions Between Opioid Drugs

There has been a controversy as to whether or not administration of opioid pure agonists with opioid agonist/antagonists will produce an interaction that diminishes the analgesic effect of the combination. There is a possibility that drugs such as butorphanol and pentazocine, which have antagonistic properties on the μ receptor, will partially reverse some effects of pure agonists such as morphine if they are administered together. The clinical relevance of this antagonism has been debated. There are few reports that have documented that such a combination is antagonistic. Reversal of the pure μ opioids can occur and acute pain or signs of opioid withdrawal may be precipitated following concurrent administration (Lascelles and Robertson, 2004).

One use of antagonistic qualities of the opioids has been to administer a μ-receptor antagonist, or partial agonist (e.g., buprenorphine) to lessen some of the dysphoric effects caused occasionally from pure μ-receptor agonists such as morphine or fentanyl, while still providing some degree of analgesia. In dogs, butorphanol can partially reverse the effects of oxymorphone (Lemke et al., 1996). Butorphanol may reverse some respiratory depression and sedation from pure agonists, but some of the analgesic efficacy is preserved. In dogs that received butorphanol for postoperative pain associated with orthopedic surgery, there was no diminished efficacy from subsequent administration of oxymorphone (Pibarot et al., 1997). However, in another study, some dogs that had not responded to butorphanol after shoulder arthrotomy responded to subsequent administration of oxymorphone, but as expected the oxymorphone dose required to produce an adequate effect was higher than what would be required if oxymorphone was used alone (Mathews et al., 1996).

Other results have been observed in cats. Increased analgesia, decreased analgesia, or no effect has been observed from combinations of agonists and antagonists. When butorphanol and oxymorphone were administered to cats in combination, there was greater efficacy than either drug used alone, with no observed antagonistic effects (Sawyer et al., 1994; Briggs et al., 1998). On the other hand, the administration of hydromorphone with butorphanol may decrease the analgesic from either drug used alone (Lascelles and Robertson, 2004). When butorphanol, buprenorphine, and the combination of both drugs were administered to cats all three treatments provided similar antinociceptive effects (Johnson et al., 2007). Although butorphanol is a κ-receptor agonist/μ-receptor antagonist, and buprenorphine is a κ-receptor antagonist/μ-receptor partial agonist, there was no antagonism detected. However, the design of the study may have prevented a more sensitive delineation of treatment effects. In general, administration of combinations of agonists and antagonist is not recommended due to variable and potential antagonistic effect.

There are data available in the human literature documenting enhanced analgesic effects and reduced tolerance by coadministering ultra-low-dose opioid antagonists with μ-agonists. The doses of the antagonists are lower than needed to completely antagonize the agonist. For example, naloxone administered as a constant rate infusion (0.25 μg/kg/h) significantly reduced the morphine consumption and gastrointestinal adverse effects in hysterectomy patients (Movafegh et al., 2012). Even lower doses have been examined in experimental animals and humans (la Vincente et al., 2008). In these studies an "ultralow naloxone" dose is in the range of 3.5 μg total dose for a 70 kg human (0.05 μg/kg). When combined with an opioid, these low doses produced significantly greater enhanced analgesia with fewer adverse effects than when the opioid was administered alone. This is in contrast to the typical naloxone dose of 0.4 mg total dose to antagonize opioid agonists in humans. Although this is an area worthy of further study in veterinary medicine, optimized doses, drug combinations, and demonstrated benefits in veterinary species are lacking.

Interactions with Drug Clearance

Opioids are high clearance drugs in animals; therefore, they rely more on hepatic blood flow than activity of liver enzymes for clearance. Diseases or conditions that impair hepatic blood flow (e.g., cardiac disease, hypotension, hypovolemia) may substantially affect opioid drug clearance. Interactions with hepatic microsomal cytochrome P450 enzymes (CYP), protein binding, or loss of hepatic function are not expected to affect most opioids' drug clearance, but some exceptions exist. The pharmacokinetics of methadone are significantly affected when combined with chloramphenicol (KuKanich and KuKanich, 2015), resulting in prolonged methadone drug exposure, higher maximum concentrations and pronounced opioid effects. The effects of chloramphenicol on other opioids likely metabolized by CYP (e.g., fentanyl, meperidine) have not been reported, but interactions could occur. An opioid not metabolized by CYP (e.g., morphine) would be a better choice until more data are available.

Renal impairment decreases the clearance of morphine glucuronide metabolites with a resultant metabolite accumulation. However, the importance of opioid glucuronide metabolites has not been demonstrated in animals and clinical consequence of metabolite accumulation has not been demonstrated in animals.

Interactions with Other Analgesics and Antidepressants

The most common drug–drug interactions with opioids occur when combined with tranquilizers/sedatives and is often used clinically to increase sedation. There is a specific interaction described in people between monoamine oxidase (MAO) inhibitors and meperidine. The interaction has been most commonly observed with older nonselective and irreversible inhibitors of MAO. The use of these drugs together has caused an unpredictable, and a sometimes fatal reaction. The reaction includes excitation, sweating, rigidity, coma, and seizures. This reaction is due to the effect of meperidine (and its metabolite normeperidine) on serotonin turnover in conjunction with the MAO inhibitors decreasing metabolism of serotonin, resulting in serotonin syndrome. This is discussed in more detail later in Section Opioid Agonists, Meperidine(Pethidine). Other analgesics that may be affected include methadone and tramadol as they also both affect serotonin turnover. The interaction with opioids that do not affect serotonin turnover (e.g., morphine, hydromorphone, fentanyl, butorphanol, etc.) is unlikely. It has been suggested if an animal is receiving an MAO inhibitor, that a test dose of the opioid should be administered. If there is no adverse reaction, subsequent doses can probably be administered safely. Although nonselective MAO inhibitors (e.g., type A and B MAO inhibitors) are rarely used in veterinary medicine for treatment of depression as they are in people, other drugs with MAO-inhibiting qualities are used in animals. For example, selegiline, a specific MAO-type B inhibitor (deprenyl, Anipryl), is used in dogs to treat canine hyperadrenocorticism and cognitive disorder (discussed in Chapter 18). A study assessing the effects of selegiline on oxymorphone and butorphanol in dogs failed to demonstrate a detrimental interaction (Dodam et al., 2004). Amitraz (Mitaban) is also a MAO-inhibitor and is found in pet collars and dips to prevent and treat mite infections in animals (see Chapter 43). Although no reactions in animals have been described between amitraz or selegiline and opioid analgesic drugs, one should be aware of a potential interaction and the animal monitored closely for adverse effects.

Uses In Food-Producing Animals

Use of other opioids in food producing animals is permitted by the Animal Medicinal Drug Use Clarification Act (AMDUCA) if an adequate withdrawal interval can be determined. Therefore the Food Animal Residue Avoidance Databank (FARAD) or a reliable reference (Papich, 1996, 2016) should be consulted prior to opioid administration to food producing species in order to obtain the most current withdrawal interval recommendations.

Opioid Agonists

Morphine

Morphine is commonly used in veterinary medicine due to its safety, efficacy, tolerability, and low cost, despite the development of newer opioids. Current dosage recommendations are presented in Table 13.7. Morphine is effective for mild to severely painful conditions. Intravenous administration results in dose-dependent increases in plasma histamine (Thompson and Walton, 1964), but at doses <0.6 mg/kg IV, no significant changes occurred in blood pressure in awake dogs (Guedes et al., 2006, 2007a). Higher doses, 3 mg/kg IV, resulted in higher plasma histamine and significant decreases in blood pressure in pentobarbital anesthetized dogs (Muldoon et al., 1984). Histamine release may possibly account for transient excitement, but it is short lived (Robinson et al., 1988; Guedes et al., 2007a). Morphine exhibits moderate protein binding in most species approximating 30%. Morphine is also produced endogenously in both humans and animals in response to inflammation and stress (Brix-Christensen et al., 2000; Yoshida et al., 2000).

Dogs

Even though the clinical morphine dose is much smaller (Table 13.7), at a dose of 3 mg/kg it showed a wide safety profile in dogs. At high doses of 40 mg/kg it produced severe coronary perfusion effects, 180 mg/kg eliciting seizures in ventilated dogs, and death at doses higher than 200 mg/kg in dogs (de Castro et al., 1979; Muldoon et al., 1984). The reported IV LD_{50} of morphine (HCl) in dogs is 175 mg/kg (Kasé et al., 1959). The pharmacokinetics of morphine were reported in several studies and are summarized in Table 13.5. Constant rate IV infusion of morphine in dog studies demonstrate the high clearance rates and need for high infusion rates (KuKanich et al., 2005c; Lucas et al., 2001; Guedes et al., 2007b). Because of its low oral and rectal bioavailability, morphine should be administered parenterally in order to consistently achieve therapeutic concentrations. The low lipophilicity in comparison to other opioids (Table 13.6) may account for the low rectal and transmucosal absorption. Morphine is also minimally absorbed following transdermal administration of a pluronic lecithin organogel formulation (Krotscheck et al., 2004). Morphine is primarily metabolized by hepatic and extrahepatic glucuronide

Table 13.7 Morphine dosages (only parenteral doses are listed, oral administration is not recommended)

	IV	IV infusion	IM/SC
Dog	0.25–0.5 mg/kg q 2–3 h	0.1–0.2 mg/kg/h	0.25–1 mg/kg q 2–4 h
Cat	0.1–0.25 mg/kg q 2–3 h	0.05–0.1 mg/kg/h	0.1–0.5 mg/kg q 2–4 h
Horse	0.1–0.2 mg/kg q 8 h	NR	0.1–0.2 mg/kg q 8 h
Sheep			≤ 10 mg total dose
Goat			≤ 10 mg total dose
Swine			0.2–0.9 mg/kg
Rat / mouse			2–5 mg/kg q 4 h
Guinea Pig / Hamster			2–5 mg/kg q 4 h
Rabbit			2–5 mg/kg q 4 h
Primates			0.5–2 mg/kg q 4–6 h
Ferrets			0.5 mg/kg q 4–6 h

NR, not recommended.

conjugation to morphine-3-glucuronide and morphine-6-glucuronide. Morphine-3-glucuronide (M3G) has little analgesic effect and may be responsible for some of the adverse effects. Morphine-6-glucuronide (M6G) has analgesic effects that are greater than the parent drug, morphine, when administered by intracerebroventricular injection. However, little of the M6G metabolite was found in canine studies (Yoshimura et al., 1993; KuKanich et al., 2005c) and its ability to penetration the CNS may be limited by the low lipophilicity in comparison to the parent drug.

A 30 to 45-minute lag time to maximum effect after 0.5 mg/kg IV morphine occurs primarily due to slow penetration into the CNS, but clinically relevant analgesia occurs within 5–15 minutes. Duration of analgesia is from 1 to 4 hours following administration of 0.25–1 mg/kg IV, IM, SC, with the length of effect approximately proportional to the dose (KuKanich et al., 2005b, 2005c). Due to the rapid and complete absorption of morphine administered IM and SC the dosing interval is the same as for IV administration.

Adverse effects associated with morphine are typical of opioids and can include sedation, emesis, hypothermia, constipation, dysphoria, pain on injection, defecation, panting, miosis, respiratory depression, and diuresis. Morphine produced vomiting in 75.7% of dogs after a dose of 0.5 mg/kg IM (Koh et al., 2014), and in 80% of dogs after a dose of 1 mg/kg (Wilson et al., 2005). Vomiting may be more frequent than other opioids, but rapid tolerance to this adverse effect develops and emesis rarely occurs with repeated administration (Valverde et al., 2004). Intravenous morphine produced transient increases in histamine release in dogs compared to other opioids, but in clinically relevant dosages minimal clinical effects are expected (Guedes et al., 2007a). Neonates are more sensitive to the respiratory depressant effects of morphine, but dogs as young as 2 days old required doses of 1 mg/kg before significant respiratory depression occurred (Bragg et al., 1995). A study examining the effect of ketoconazole on morphine pharmacokinetics in Greyhounds indicated no dose adjustments are needed for this breed or when ketoconazole is administered concurrently with morphine (KuKanich and Borum, 2008a).

Cats

Morphine is well tolerated in cats, rarely producing CNS excitation when administered in clinically recommended doses. Laboratory studies administered cats morphine at a dose of 3 mg/kg SC which did not produce excitement, but 5–10 mg/kg SC produced signs of CNS excitation and 20 mg/kg SC produced consistent "morphine mania" after administration (Sturtevant and Drill, 1957.) Morphine, 2 mg/kg IM, was well tolerated with mydriasis, sedation, pacing, pouncing, emesis, and fascination with water being noted as adverse effects, but CNS excitation and "morphine mania" were not noted in the study (Barr et al., 2000, 2003). Clinically recommended morphine doses, 0.2 mg/kg, produced vomiting in healthy cats, but otherwise did not produce dysphoria or excitement (Steagall et al., 2006). Instead, the cats exhibited euphoria with purring, kneading, and increased affection.

The primary metabolite of morphine in cats are sulfate conjugates because cats are deficient in glucuronidation of some compounds compared to other species (Yeh et al., 1971). The lack of glucuronide conjugate formation in cats is not unexpected, but the metabolism is still rapid in cats and indicative of a high extraction drug. Pharmacokinetic studies in cats have indicated a smaller volume of distribution and slower clearance as compared to dogs, with the elimination half-life being nearly identical (KuKanich et al., 2005a; Taylor et al., 2001; Pypendop et al., 2014). Assuming cats respond to the analgesic effects of morphine at similar concentrations as other animals, 0.2–0.3 mg/kg IV, IM, SC every 3–4 hours would produce similar plasma concentrations as other animal species.

Studies examining the effects of morphine on feline immunodeficiency virus(FIV) infected cats produced unexpected results. Morphine, 1–2 mg/kg administered once daily subcutaneously on 2 consecutive days per week, significantly reduced the clinical signs associated with FIV infection including delayed lymphadenopathy, CNS deterioration, and a trend towards decreased viral load (Barr et al., 2000, 2003). Clinical trials in naturally infected cats have not been conducted.

Horses

Morphine has been safely administered to horses under some conditions, but reports of excitement, behavior changes, and sustained increased locomotor activity have limited its routine use for pain control. Reports of excitement following morphine administration to horses may be caused by doses that were too high or lack of concurrent sedatives (e.g., α_2-agonists or tranquilizers) administered. In comparison to other species, horses seem to be the most prone to excitation/ increase locomotor activity as an adverse effect. Morphine, 0.1–0.25 mg/kg IV, as a sole agent has been administered with no reported excitement and resulted in decreased anesthetic consumption, produced minimal hemodynamic, and minimal blood gas effects (Devine et al., 2013; Clark et al., 2005; Bennett et al., 2004; Steffey et al., 2003; Combie et al., 1983; Muir et al., 1978). However higher doses, 0.66 mg/kg and above, resulted in adverse effects of blood gas measurements, dysphoria, and excitement, and therefore should be avoided (Brunson and Majors, 1987; Kalpravidh et al., 1984). Coombie et al. (1983) recommended morphine should not be administered less than 7 days prior to a race as it is detectable in the urine at

144 hours (6 days). The regulation of drugs used in racing animals is discussed in more detail in Chapter 57. Repeated doses of morphine should be used extremely cautiously in horses due to its constipating effect and the potential for impaction and colic.

Ruminants

The clinical use of morphine in ruminants in rare. The lack of residue depletion studies, controlled substance status, and the potential to decrease rumen contractions have limited its use.

Swine

Morphine has been associated with CNS excitation in swine, but like other species is likely to be related to the dose administered. The clinical use of morphine in swine is limited by the lack of residue depletion studies and controlled substance status, but with increasing numbers of swine as companion animals (e.g., pot-bellied pigs) and in research settings the use of morphine in this species may increase.

Small Mammals

Morphine has been used in rats, mice, guinea pigs, and ferrets as an analgesic, preanesthetic, and sedative. Analgesic effects are rapid following IM and SC administration typically occurring within 15 minutes and lasting up to 4 hours, similar to other species.

Rabbits

Morphine has been previously reported to produce profound sedation in rabbits when administered 8 mg/kg IM as a preanesthetic. However, pharmacokinetic studies indicate analgesic dosages are probably in the range of 2–4 mg/kg IM or SC every 4–6 hours.

Fish

Morphine has been used in fish to control pain (Sneddon, 2003). Fish not only feel pain (Sneddon et al., 2003), but they also appear to have opiate receptors. However, one study in which morphine was administered at high doses also reported that there were significant adverse cardiovascular effects (Newby et al., 2007). Fish appear to have slower clearance rates than mammals. In one study (Newby et al., 2006) clearance rates were 25 to 50 times slower than dogs, and mean residence times were 7 hours and 27 hours in two species of fish.

Nonhuman Primates

Nonhuman primates require relatively large doses of morphine, 1–2 mg/kg, for sedation. However nonhuman primates also appear to be relatively resistant to respiratory depression at these dosages despite high plasma concentrations (Lynn et al., 1991). Analgesic dosages are more likely in the range of those recommended for dogs.

Hydromorphone

Hydromorphone is a morphine derivative with similar lipophilicity, but greater potency compared to morphine (Murray and Hagen, 2005) (Tables 13.6 and 13.8). Hydromorphone is approximately seven times more potent than morphine with a similar duration of effect. Hydromorphone has high intrinsic activity at the μ-opioid receptor. The effectiveness for mild to severe pain is similar to morphine and oxymorphone with equipotent doses (Smith et al., 2001) (0.11 mg/kg for oxymorphone; 0.22 mg/kg for hydromorphone). Hydromorphone produced less of an emetic effect than morphine in some studies, but a high incidence in other studies. As cited above for morphine, vomiting rates are high. After hydromorphone administration the incidence of vomiting was 25% in one study (Hay Kraus, 2014a), but much higher in other studies (Claude et al., 2014; Hay Kraus, 2014b). Hydromorphone produced less histamine compared to equipotent morphine doses (Guedes et al., 2006). In dogs, hydromorphone pharmacokinetics were reported between 0.1 and 0.5 mg/kg IV, SC (Guedes et al., 2008; KuKanich et al., 2008a). The pharmacokinetics were similar to morphine in dogs (Table 13.5), with a short half-life, high volume of distribution, and high clearance that exceeded hepatic blood flow. Significant differences in the pharmacokinetics of hydromorphone occurred between 0.1 and 0.5 mg/kg with the higher dose resulting in significantly decreased clearance and prolonged half-life (KuKanich et al., 2008a). Antinociception was detected for at least 2 hours at 0.1–0.2 mg/kg IV, and may be up to 4–6 hours depending on the dose, degree of pain, and individual animal variability (Guedes et al., 2008).

The pharmacokinetics and pharmacodynamics of hydromorphone have been investigated in cats (Table 13.5) in which a rapid clearance and short half-life were determined, similar to morphine (Wegner et al., 2004; Wegner and Robertson, 2007; Pypendop et al.,

Table 13.8 Comparable potency of opioids

Drug	Brand Name	Potency [a]
Morphine	Generic	1
Codeine	Generic	0.1
Meperidine	Demerol	0.16
Propoxyphene	Darvon	0.16–0.3
Butorphanol	Torbugesic	1–7
Hydrocodone	Vicodin	6
Oxycodone	Percocet, Oxy-Contin	3–6
Oxymorphone	Numorphan	10–15
Hydromorphone	Dilaudid, generic	8
Buprenorphine	Buprenex	25
Fentanyl	Sublimaze	100

[a] Potency is based on relative potency in comparison to morphine.

Table 13.9 Hydromorphone dosages (only parenteral doses are listed, oral administration is not recommended)

	IV	IV infusion	IM/SC
Dog	0.05–0.1 mg/kg q 2–4 h	0.02–0.04 mg/kg/h	0.1 mg/kg q 2–4 h
Cat	0.05–0.1 mg/kg q 2–4 h	0.02–0.03 mg/kg/h	0.05–0.1 mg/kg q 2–4 h
Horse	0.01–0.02 mg/kg once	NR	0.01–0.02 mg/kg once
Rat / mouse			0.3–0.7 mg/kg q 4h
Guinea pig / hamster			0.3–0.7 mg/kg q 4h

Primates			0.1–0.3 mg/kg q 4–6h
Ferrets			0.05–0.1 mg/kg q 4–6h

NR, not recommended.

2014). Although analgesic effects produced had a duration of up to 8 hours in the experimental model, it is unlikely these correlate with clinical analgesia. The recommended starting dosage interval for hydromorphone is the same as morphine, every 2–4 hours in dogs and cats, but may be up to 6 hours depending on pain severity and individual animal differences. Hydromorphone is associated with hyperthermia in cats, but hyperthermia has been reported with other opioids including morphine, buprenorphine, and butorphanol (Posner et al., 2007; Niedfeldt and Robertson, 2006). Hyperthermia associated with hydromorphone has been as high as 41–42°C (107–108°F) in cats, and can last for as long as 5 hours.

Hydromorphone is available as oral syrup and tablets as hydromorphone hydrochloride. Although the pharmacokinetics of the oral formulations have not been reported for dogs or cats, the oral bioavailability is expected to be low or negligent because of the high first-pass clearance. Hydromorphone hydrochloride injection is widely available and commonly used in veterinary medicine. Current dose recommendations for hydromorphone are presented in Table 13.9.

Oxymorphone

Oxymorphone is a morphine derivative with 10 times the potency of morphine (Table 13.8) and similar lipophilicity. Oxymorphone produces less emesis, nausea, and sedation than morphine and hydromorphone when administered at equipotent doses to dogs and cats. Oxymorphone also causes less histamine release in dogs (Robinson et al., 1988; Smith et al., 2001). Oxymorphone is primarily eliminated as drug conjugates (56% of total dose) with small amounts eliminated unchanged in the urine (5.3%) or as 6-keto reduction metabolites (1.6%) in dogs. The pharmacokinetics of oxymorphone in dogs are similar to other opioids such as morphine and hydromorphone with a large volume of distribution, rapid clearance, and short half-life (KuKanich et al., 2008b). The maximum concentration, 21.5 ng/ml, occurred at approximately 10 minutes, after 0.1 mg/kg SC with an elimination half-life of 1 hour. The pharmacokinetics in cats (Table 13.5) indicate that clearance is slower and half-life slightly longer than dogs (Pypendop et al., 2014).

Oxymorphone, 0.03 mg/kg IV, produced similar effects in horses as morphine. Although a veterinary formulation is FDA approved, it is not currently available. Intermittent availability problems with the human approved products have also occurred. Oxymorphone is not used commonly due to intermittent supply problems and cost. Current dose recommendations for oxymorphone are presented in Table 13.10.

Hydrocodone

Hydrocodone is a morphine derivative primarily used as an antitussive, but may also be effective for mild to

Table 13.10 Oxymorphone dosages (only parenteral doses are listed, oral administration is not recommended)

	IV	IV infusion	IM/SC
Dog	0.05–0.1 mg/kg q 2–4 h	0.005–0.01 mg/kg/h	0.05–0.1 mg/kg q 2–4 h
Cat	0.025–0.05 mg/kg q 2–3 h	0.01–0.02 mg/kg/h	0.025–0.11 mg/kg q 2–4 h
Horse	0.01–0.02 mg/kg once	NR	0.01–0.02 mg/kg once
Rat / mouse			0.2–0.5 mg/kg q 4 h
Guinea pig/ hamster			0.2–0.5 mg/kg q 4 h

Primates			0.05–0.2 mg/kg q 4–6
Ferrets			0.05 mg/kg q 4–6 h

moderate pain. Hydrocodone appears to have the highest oral bioavailability of the opioids studied. The efficacy of hydrocodone is in part due to metabolism to hydromorphone, which occurs in dogs (Findlay et al., 1979; Barnhart and Caldwell, 1977). Demethylation of hydrocodone to hydromorphone is more prominent in dogs than the demethylation of codeine to morphine (Findlay et al., 1979). However, there appears to be variability in the metabolism of hydrocodone to hydromorphone with some studies reporting substantial amounts of hydromorphone produced (KuKanich and Spade, 2013; Findlay et al., 1979; Barnhart and Caldwell, 1977), whereas others report it is not a substantial metabolite (Benitez et al., 2015a; Li et al., 2013). Norhydrocodone has been identified as a metabolite in dogs after high doses (60–120 mg/day in unstated dog breed or weight) and it does have some μ opioid effects, about 70 times less potent than hydrocodone itself (Li et al., 2013; Navani and Yoburn, 2013). The absolute oral bioavailability of hydrocodone (34–44%) is also higher in dogs than codeine (6–7%) (Findlay et al., 1979). This may explain why many veterinarians prefer oral hydrocodone as an antitussive treatment over codeine in dogs.

Hydrocodone is available for oral use (syrup and tablets) as hydrocodone bitartrate. Preparations that contain hydrocodone for oral use in people in the United States may also contain homatropine (Hycodan) or acetaminophen and a recently approved version contains hydrocodone as a sole ingredient. Hydrocodone also is available with nonsteroidal antiinflammatory drugs (Table 13.11).

When administered as an antitussive, the homatropine is not expected to have therapeutic or adverse effects that affect coughing, but is included as an abuse deterrent. The recommended dose for dogs as an antitussive is 0.22 mg/kg of hydrocodone every 4–8 hours; for analgesia higher doses are likely to be needed, 0.44 mg/kg every 6–8 hours. A recent study reported the clinical efficacy of hydrocodone in combination with acetaminophen in postoperative orthopedic surgery dogs in which 15/25 were judged as having adequate analgesia using a subjective scale (Benitez et al., 2015b).

Table 13.11 Examples of opioids combined with nonsteroidal antiinflammatory drugs (NSAIDs)

Opioid	NSAID	Common brand name
Hydrocodone	Acetaminophen	Vicodin, Hydrocet, Lorcet
Codeine	Acetaminophen	Tylenol with Codeine
Codeine	Aspirin	Empirin
Hydrocodone	Aspirin	Damason
Oxycodone	Aspirin	Percondan
Oxycodone	Acetaminophen	Percocet, Tylox, Roxicet

Codeine

Codeine is a naturally occurring alkaloid similar in structure to morphine. Because of the availability of other opioids, parenteral codeine is rarely indicated for use in veterinary medicine, with codeine's use primarily limited to oral administration for mild pain most often in combination with acetaminophen (Table 13.11). The combination with acetaminophen is contraindicated in cats as acetaminophen is toxic.

There are multiple metabolites of codeine, for example the 6-glucuronide, norcodeine, and morphine. In people, approximately 10% of codeine is metabolized to morphine, via *O*-demethylation, but may be much lower than previously assumed (Shah and Mason, 1990). Morphine is further metabolized to other compounds in people, which may be active (i.e., morphine-6-glucuronide). It has always been assumed that the activity of codeine was produced by morphine or its metabolites, thus it would have approximately 10% of the efficacy of morphine. However, more recent evidence suggests that other metabolites (for example codeine-6-glucuronide and norcodeine) may contribute to codeine's analgesic activity (Lötsch et al., 2006). In dogs, the absolute oral bioavailability of codeine is low (4–7%) and morphine is a minimal metabolite, but there is substantial codeine glucuronidation in dogs (KuKanich, 2010; Findlay et al., 1979). The analgesic efficacy of oral codeine has not been examined in clinical trials with dogs or cats.

Oxycodone

Oxycodone is a morphine derivative with mild to moderate analgesic effects. In humans oxycodone has a 50–70% oral bioavailability and is available as an extended-release tablet (Table 13.11). Clinical use of oxycodone in animals has not been evaluated. Similar to the pattern observed for other opiates in dogs, oral systemic absorption is low. A dose of 0.5 mg/kg resulted in a C_{MAX} of only 6.5 ng/ml at 15 min and was below the limit of quantification (0.625 ng/ml) by 3 hours (Weinstein and Gaylord, 1979). However, only two dogs were evaluated. Noroxycodone was identified as a primary metabolite, but is 30 times less active than oxycodone. Oxymorphone was not assessed as a metabolite in dogs, but is a minor metabolite in humans (Söderberg et al., 2013). The low oral systemic availability would likely result in poor efficacy; therefore, its use is not currently recommended. It also has high abuse potential in people and would be risk if stocked in veterinary hospitals.

Heroin

Heroin is the diacetyl congener of morphine and is widely abused by humans. Heroin is available for medical use in some countries, but does not possess greater analgesic activity than morphine. The lipophilicity of heroin is greater than that of morphine resulting in a faster onset of action and the rapid euphoric effect following IV administration. Heroin is rapidly metabolized to morphine in most species. Although there is some historical use of heroin in veterinary medicine, current administration of heroin in veterinary medicine is not recommended due to the high abuse potential and it is listed as a Schedule I drug by the United States DEA (Table 13.2).

Methadone

Methadone has traditionally been used in humans to treat opiate addiction (Kosten and O'Connor, 2003). It was first shown to have this property in 1948 and was adopted as one of the principal treatments for opiate addiction in 1965. The advantage of methadone in this use is that the severity of withdrawal signs from methadone is much less than from heroin. It also has a much longer half-life in people (approximately 24 hours) than morphine or heroin and has high oral bioavailability. Therefore, addiction treatment programs can administer methadone once a day orally to avoid intravenous injections and achieve good compliance rates. At one time, methadone's only common use was for treatment of opiate addiction. However, it is now considered a valuable analgesic drug as well.

Methadone is approved for use in dogs by some countries. Methadone is a μ-receptor opiate agonist with high intrinsic activity. Methadone also has some activity as an antagonist at NMDA receptors and inhibits reuptake of norepinephrine and serotonin, all of which contribute variably to its analgesic activity. As a result, pain that is poorly controlled with other opioids (morphine, hydromorphone, and fentanyl), such as chronic and neuropathic pain, may be controlled more effectively with methadone (Foley, 2003). Activity on the NMDA receptor decreases tolerance from developing to the opiate effects. Additionally, methadone has demonstrated synergistic analgesic effects when coadministered with morphine and additive effects when administered in combination with oxymorphone, oxycodone, fentanyl, alfentanyl, or meperidine (Bolan et al., 2002). Methadone is a 50 : 50 racemic mixture, with the L-chiral isomer (L-enantiomer) primarily responsible for the opioid pharmacological effect and both isomers, L- and D-methadone, capable of binding to the NMDA receptor. Levomethadone contains only the L-enantiomer, therefore the administered dose should be half of the racemic formulation. Although oral formulations of methadone are inexpensive and readily available, the oral bioavailability is low and produced inconsistent plasma concentrations after oral administration to dogs (KuKanich and KuKanich, 2015; KuKanich et al., 2011, 2005d). Although not specifically studied in cats, the oral bioavailability may be higher in cats as the clearance suggests it is not a high hepatic extraction ratio drug (Pypendop et al., 2014) (Table 13.5).

Methadone appears to be well tolerated in dogs following IV administration, with adverse effects routinely occurring with morphine such as nausea, vomiting, defecation, and dysphoria not reported with methadone. Sedation was a prominent adverse effect and, as with other μ-receptor agonists, dose-dependent respiratory depression occurs, which is typically clinically insignificant with appropriate dosages (KuKanich et al., 2005d; KuKanich and Borum, 2008b; Garafolo et al., 2012). Cardiovascular effects are noted in healthy dogs following clinically relevant methadone dosages (0.5–1 mg/kg IV), with decreased cardiac output (~20%) and increased systemic vascular resistance (~50–100%) (Maiante et al., 2009; Stanley et al., 1980). The methadone LD_{50} in dogs (29 mg/kg IV) is proportionally lower relative to the clinical dose (0.5 mg/kg IV) than morphine (LD_{50} = 175 mg/kg IV, clinical dose = 0.5 mg/kg IV), but the LD_{50} is still 60 times higher than the clinical dose (Kasé et al., 1959). Thus, methadone has a large safety margin in healthy dogs, but should be administered cautiously in animals prone to congestive heart failure, with underlying cardiac disease, or hypertension.

The analgesic potency of methadone is similar to that of morphine (Table 13.8) and as a result the administered dose range is similar. However, the elimination of methadone is slower, resulting in longer dosing intervals as compared to morphine. The recommended dose of methadone for dogs is 0.5 mg/kg IV every 4–6 hours or 0.5–1 mg/kg every 6–8 hours IV, IM, SC. A study of methadone in Greyhounds indicated methadone is rapidly eliminated after IV administration in this breed with a higher dose and more frequent administration recommended 1 mg/kg q 3–4 hours (KuKanich and Borum, 2008b). Repeated IM and SC injections may result in tissue irritation and inflammation.

In cats, methadone, 0.6 mg/kg IM, was well tolerated when administered as a preanesthetic (Bley et al., 2004) and was effective for postoperative pain at a dose of 0.5–0.6 mg/kg (Dobromylskyj, 1993; Bley et al., 2004). Although repeated doses were not evaluated, a suggested dose interval based on pharmacokinetics and clinical observations is every 6–8 hours in cats. At a dose of 0.2 mg/kg SC to healthy cats, there were no adverse effects observed, euphoria was exhibited, and it was as effective against nociceptive stimuli as morphine (Steagall et al., 2006). At higher doses of 0.6 mg/kg SC, in the perioperative setting, it provided better analgesia than butorphanol in cats and was well tolerated (Warne et al., 2013). Administered via the oral transmucosal route to cats at a dose of 0.6 mg/kg, it was well tolerated and provided antinociceptive effects similar to the intravenous route (Ferreira et al., 2011).

Methadone appears to be well tolerated in horses when administered up to 0.2 mg/kg IV in combination with an α-2 agonist (Schatzman et al., 2001; Nilsfors et al., 1988). It was administered to horses at a dose of 0.15 mg/kg by the oral route, intragastric route, and IV and was well tolerated at concentrations that are similar to those considered analgesic for people (Linardi et al., 2012). No behavioral effects such as excitement, sedation, increased locomotor activity, or decrease gastrointestinal tract activity associated with other opioids were observed with methadone. The half-life was approximately 1 hour with a moderate volume of distribution. When methadone was administered through a nasogastric tube oral absorption was low (30%), but the absorption was much higher from administration directly into the mouth, suggesting oral transmucosal absorption occurred (Linardi et al., 2012). It also has been used in horses with ketamine protocols and as an anesthetic adjunct. Minimal cardiovascular effects were observed and as expected there was an increase in sedation with the combination as compared to the α-2 agonist alone. Healthy, pain-free horses administered methadone (0.12 mg/kg IV) as a sole agent showed increases in heart rate, arterial blood pressure, and cardiac output, but only minimal effects on blood gas parameters. Euphoria and dysphoria was of approximately 15 minutes in duration, but was subjectively less than the same effects produced by morphine, meperidine, and oxymorphone, but similar to that of pentazocine (Muir et al., 1978). An advantage of methadone in horses is that at doses in the range of 0.1 mg/kg, IV, sedation occurs, but they did not become recumbent. The horses maintained a sedated standing position without incoordination, allowing minor procedures to be performed.

Methadone is available as an oral flavored concentrate 1–10 mg/ml, as tablets for suspension (40 mg), and as oral tablets (5, 10 mg). It is also available as an injectable solution (10 mg/ml).

Meperidine (Pethidine)

The availability of newer opioids has resulted in a dramatic decrease in the use of meperidine in veterinary medicine. Meperidine (meperidine is the USAN terminology, but pethidine is used in the BAN) is a synthetic opioid with antimuscarinic and negative inotropic effects that are different from most of the other opioids. Meperidine appears to have the most cardiac depressant effects of the opioids. Similar to morphine, histamine release occurs following IV administration, but the clinical relevance appears to be minimal as adverse effects were not reported following intravenous meperidine administered to dogs (2 and 5 mg/kg) or cats (11 mg/kg) (Ritschel et al., 1987; Davis and Donnelly, 1968). Meperidine is less potent than morphine, therefore higher doses are needed (Table 13.8). It may be less constipating and cause less nausea than morphine. A meperidine metabolite, normeperidine, has CNS excitatory effects and accumulates following multiple doses in humans and can result in seizures. This metabolite in people has contributed to the *serotonin syndrome* that is associated with some drugs and drug combinations and is a precaution to its use in human medicine today. However, normeperidine appears to be a minor metabolite in dogs and cats. Meperidine as the parent drug can also exhibit some effects on serotonin receptors and can result in serotonin syndrome if combined with a monoamine oxidase inhibitor (selegiline), tricyclic antidepressant, serotonin reuptake inhibitor, or tramadol. Pharmacokinetics are summarized in Table 13.5. Meperidine is well absorbed following IM administration to dogs and cats, but the rate of absorption is variable. Meperidine has poor oral and transmucosal bioavailability in dogs.

Meperidine (1.1 mg/kg IV) produces similar adverse effects in horses as morphine (0.1 mg/kg). The duration of analgesia is approximately 1 hour as meperidine is rapidly redistributed following IV administration. The elimination half-life is 1 hour and multiple doses would be expected to result in drug accumulation, longer duration of effect, and increase the risk of altered gastrointestinal tract motility.

Fentanyl

Fentanyl is a synthetic opioid that is selective for the μ-opioid receptor. Its use has increased in veterinary medicine as an intravenous drug and transdermal preparation. Similar to other opioids, fentanyl has minimal cardiovascular effects at clinically relevant dosages in healthy animals. There is a dose-dependent respiratory depression, but this is not a clinical problem in healthy veterinary species (Grimm et al., 2005; Hug and Murphy, 1979). Fentanyl has a wide safety profile with doses as high as 300 times the recommended dose not being lethal in spontaneously breathing dogs (Bailey et al., 1987). Even when high-dose fentanyl transdermal delivery was administered to dogs undergoing surgery, fentanyl did not produce postoperative respiratory depression (Welch et al., 2002). It is highly lipophilic – more than 1,000 times more lipophilic than morphine (Table 13.6). As a result, the onset of action is rapid in comparison to the other opioids because of rapid diffusion into the CNS. Fentanyl CSF concentrations peak between 2.5 and 10 minutes following IV administration, in comparison to morphine which peak between 15 and 30 minutes in dogs. Due to the rapid penetration into the CNS, effects on the respiratory center occurs immediately following IV fentanyl

Table 13.12 Fentanyl dosages

	IV	IV infusion	IM/SC
Dog	5–10 µg/kg q 1–3 h	2–5 µg/kg/h	5–15 µg/kg q 1–3 h
Cat	5–10 µg/kg q 1–3 h	2–5 µg/kg/h	5–10 µg/kg q 1–3 h
Horse	2–4 µg/kg q 3–4 h	0.3–0.5 µg/kg/h	2–4 µg/kg q 3–4 h

Note: Dosages are in µg/kg. 1000 µg = 1 mg.

administration. Fentanyl is primarily eliminated by metabolism, with hydroxylation and dealkylation being the primary mechanisms, and less than 8% of the total dose eliminated as unchanged drug. Pharmacokinetics are summarized in Table 13.5 and current dose recommendations for fentanyl are presented in Table 13.12.

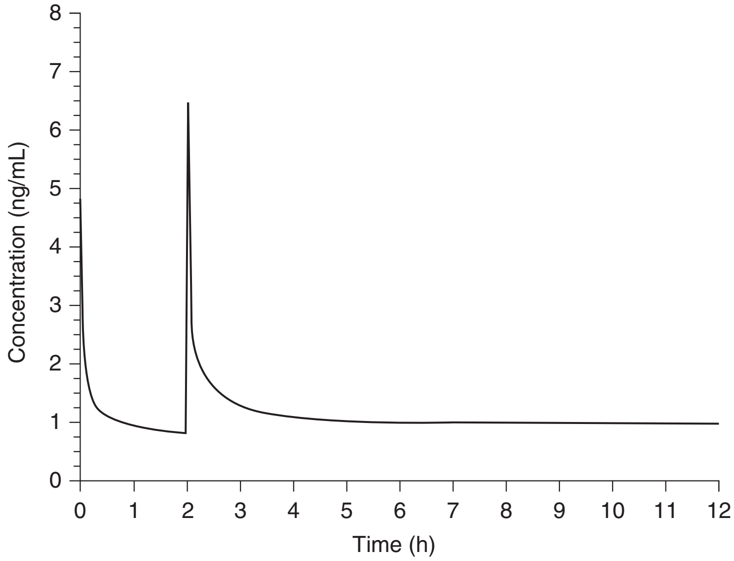
As a very lipophilic molecule with high potency (Table 13.8), fentanyl is ideally suited for transdermal penetration to produce systemic effects. A veterinary approved fentanyl transdermal solution is available for use in dogs and a transdermal delivery device, generally referred to as the "fentanyl patch," which bypasses first-pass hepatic metabolism resulting in therapeutic plasma concentrations, is used in an extralabel manner in cats and dogs.

Dogs

Fentanyl is well tolerated in dogs with a lower occurrence of nausea, vomiting, and dysphoria as compared to some of the other opioids, but variable sedation has been observed. In dogs fentanyl is about 60% bound to plasma proteins and protein binding is linear with plasma concentration. Pharmacokinetics are listed in Table 13.5. Following IV bolus administration, plasma fentanyl concentrations decrease rapidly, primarily due to redistribution with a concurrent rapid decrease in the effects. The distribution half-life is approximately 45 minutes (Kyles et al., 1996). This phenomenon is similar to that seen with thiobarbiturates where redistribution from the CNS is primarily responsible for recovery from anesthesia. There is a more prolonged terminal phase with a mean elimination half-life in dogs of up to 6 hours (KuKanich and Allen, 2014; Kyles et al., 1996), indicating steady-state plasma concentrations will be achieved at 18–24 hours if administered as an IV infusion. In order to rapidly achieve and maintain targeted plasma concentrations, a loading dose of fentanyl is recommended at the beginning of an IV infusion and may need to be repeated, especially in severely painful animals (Figure 13.2). Subcutaneous fentanyl is rapidly absorbed with plasma concentrations exceeding 0.5 ng/ml persisting for about 4 hours after 15 µg/kg SC (KuKanich, 2011). Pain occurs on SC injection because the formulation of fentanyl citrate can be irritating to tissues, but addition of sodium bicarbonate (8.4%) at a ratio of 1 part sodium chloride to 20 parts fentanyl injection eliminated the pain associated with the injections.

Transdermal fentanyl solution (Recuvyra®) is approved for use in dogs with expected analgesic effects occurring within 2–4 hours and persisting for about 96 hours. However, there can be a variation in response because of interanimal variability in the extent of absorption and duration of effects. A risk minimization action plan (RiskMAP) is required for safe and appropriate use of the transdermal solution since it is highly concentrated (50 mg/ml compared to 0.05 mg/ml for the conventional injection of fentanyl citrate). It is absorbed through intact skin and human exposure could result in serious and potential life-threatening respiratory depression. Specific requirements must be met for its application: two trained people are required for administration, a specific applicator and syringe are

Figure 13.2 The expected plasma profile of fentanyl administered as two loading doses, 5 µg/kg IV, at time 0 and 2 h and IV infusion 2 µg/kg/h starting at time 0 in dogs. The second IV loading dose is administered to prevent drug concentrations from dropping below 1 ng/ml. The targeted plasma concentration of fentanyl is 1 ng/ml for analgesia.



required for administration, protective clothing (lab coat, safety glasses, and impermeable gloves) are required, the solution should only be applied in a hospital setting, animals treated with the transdermal solution should be gently restrained for 5 minutes to allow the solution to dry, and hospital staff should wear impermeable glove when handling the treated dogs. Due to the variability in drug absorption a small percentage of treated dogs may need rescue analgesia and some dogs may have profound opioid effects in which naloxone is effective at reversing.

Fentanyl is well absorbed, but variably, in dogs when administered by a transdermal patch (Kyles et al., 1996) with patches requiring changing every 72 hours (3 days) to maintain a therapeutic effect. There is a 12 to 24-hour lag time before therapeutic effects are achieved following patch application, consistent with the time needed to achieve steady state from an IV infusion, as noted above, resulting in effective concentrations for 2 day, from 24 to 72 hours. Although the fentanyl patches are not approved for animals, the human sizes are used. Fentanyl patches are available in sizes of 12.5, 25, 50, 75, and 100 μg/h delivery rates. Despite this range of sizes, there have been no differences observed in plasma concentrations in dogs when 50-μg/h patches were compared with 100-μg/h patches (Egger et al. 1998). High-dose patches were well tolerated in dogs (Welch et al., 2002) and have been effective for treating both soft-tissue and orthopedic surgical pain in dogs (Robinson et al., 1999; Kyles et al., 1998). Fentanyl patches should be prescribed cautiously as diversion, abuse, and accidental exposure could occur when used for outpatients. People have died after leaving the hospital because they were sensitive to fentanyl and developed respiratory depression. Death in children have been reported due to exposure to fentanyl transdermal patches. Despite the evidence for absorption of fentanyl from a patch or the transdermal solution, fentanyl formulated in a pluronic lecithin organogel (PLO) transdermal gel failed to reach 1 ng/ml, indicating it is not an effective formulation in dogs (Krotscheck et al., 2004).

Cats

Cats have tolerated fentanyl well with only mild adverse effects that have included sedation, purring, rubbing, kneading, and mydriasis (Robertson et al., 2005a). The total body clearance of fentanyl is similar to that of dogs, but because of a much lower volume of distribution, the elimination half-life is much shorter (~2.5 hours) (Lee et al., 2000). The fentanyl transdermal solution approved for dogs should not be administered to cats because there are differences in drug absorption. Fentanyl is also well absorbed, but variably, in cats from the transdermal patch (Lee et al., 2000). Doses most often used for fentanyl patches in cats are the 25-μg/h patch. In very small cats, a 12.5-μg/h patch can be used or one-half of a 25-μg/h patch can be covered (absorption is dependent on the exposed surface area of the patch) resulting in a rate of delivery reduced by approximately one-half (Davidson et al., 2004).

Because of the shorter half-life in cats, there is a 6 to 12-hour lag time to therapeutic effect following application of fentanyl patches, which is shorter than in dogs. In contrast to dogs, the drug concentrations persist longer in the skin of cats, resulting in a longer terminal half-life after fentanyl patches are removed (Lee et al. 2000). Therapeutic plasma concentrations can be maintained for 120 hours (5 days) in cats after administration of a 25-μg/h patch. Clinical studies have demonstrated efficacy of transdermal fentanyl in cats for pain from surgical onychectomy (Gellasch et al., 2002; Franks et al., 2000).

Horses

Although fentanyl has been administered IV in some analgesic and anesthetic protocols for horses, it is not used as often as other opioids. When fentanyl is administered IV to horses, it is relatively well tolerated, but stimulation of locomotor activity has been well documented at 20 μg/kg (Mama et al., 1992) and at even lower doses of 5 μg/kg (Kamerling et al. 1985).

The use of fentanyl transdermal delivery is not as practical in horses as it has been in dogs and cats. Fentanyl is well absorbed following application of transdermal patches in horse (Maxwell et al., 2003), but concentrations are variable and short lived. When two 100-μg/h fentanyl patches were applied to horses, there was high absorption and plasma concentrations that were in a range considered to be therapeutic, but not as long lasting as in small animals. In another study, after application of three 100-μg/h patches to horses, the concentrations were in a therapeutic range, but were variable (Orsini et al., 2006). There was a peak at approximately 12 hours, but thereafter it declined during the next 72 hours without attaining a steady-state plateau as seen in the smaller animals.

Application of fentanyl patches to horses for controlling pain has produced mixed results. Low doses delivered by one or two 100-μg/h patches have not produced consistently effective results. Fentanyl was capable of controlling visceral pain in horses without producing adverse effects, but that somatic musculoskeletal pain was less effectively controlled, or may require higher doses (Orsini et al., 2006). Thomasy et al. (2004) found that transdermal fentanyl controlled musculoskeletal pain in some horses that had not responded to nonsteroidal antiinflammatory drugs (NSAIDs) alone, but improvement was minimal. In the study by Orsini et al. (2006) they concluded that a minimum of three 100-μg/h patches are necessary to control pain in horses, and some horses may not respond. To maintain effective concentrations, patches should be reapplied every 36 to 48 hours, in contrast to dogs, cats, and people. Alternatively, the authors propose (Orsini et al., 2006) that patches should not be removed for 100 hours but new ones applied during treatment at 36 hours and every 24 hours thereafter.

Other Large Animal Species

Fentanyl also has been investigated as an anesthetic adjunct and analgesic in sheep, goats, and llamas. In the study by Grubb et al. (2005) the application of four 75-μg/h fentanyl patches produced plasma fentanyl concentrations judged to be in a therapeutic range and it was well tolerated.

Fentanyl was administered IV and via transdermal patch to goats (Carroll et al., 1999). Although the IV half-life was short (1.2 hour mean), it was otherwise well tolerated. A single 50-μg/h transdermal patch produced plasma concentrations in an effective range, but the results were highly variable among goats. Plasma concentrations were not sustained at a steady-state level that has been observed in other animals.

Sufentanil, Alfentanil, Remifentanil

Sufentanil, alfentanil, and remifentanil are fentanyl derivatives that exhibit similar pharmacodynamic effects as fentanyl. Sufentanil is five to seven times more potent than fentanyl and eliminated metabolically similar to fentanyl. Alfentanil is a fentanyl derivative that is less potent, but eliminated in a similar manner. Remifentanil is unique among the fentanyl derivatives as it undergoes nonhepatic metabolism due to esterases in the tissues (primarily muscle and intestinal) and plasma resulting in a short terminal half-life of only 3–6 minutes and a rapid clearance in dogs. Clinical use of remifentanil is uncommon but it can be used during induction anesthetic protocols and administered with a constant rate infusion. Because of the short half-life, steady-state concentrations are achieved rapidly. It can be administered with other drugs, including inhalant anesthetics, propofol, α_2-agonists, sedatives, and tranquilizers. Because it does not require hepatic metabolism or renal elimination, it can be administered safely to patients that have liver or kidney disease. Remifentanil use in dogs is limited to a few studies and case reports. Doses in animals have been extrapolated from humans (human starting dose is 0.1 μg/kg/min constant rate infusion). Remifentanil has been infused safely in cats, and over a wide range of doses (0.06–16 μg/kg/min) IV it did not affect isoflurane minimum alveolar concentration (MAC).

Carfentanil and Etorphine

Carfentanil and etorphine are opioid agonists primarily used for sedation and capture of zoo and wild animals. For a complete discussion of the use of these drugs for this indication, the reader is referred to more detailed book chapters (Carpenter and Brunson, 2007; Caulkett and Arnemo, 2007). Carfentanil is a very potent fentanyl derivative used primarily for immobilization of zoo and wildlife species. It is reported to be 8,000–10,000 times more potent than morphine. Carfentanil is a DEA schedule II controlled substance with additional registration and storage requirements, which must be met prior to obtaining it. The capture dose is 0.005–0.02 mg/kg and carfentanil is available as a 3-mg/ml solution. The high potency of carfentanil allows specialists in this field to administer small volumes via projectile dart.

Etorphine (M99) has a potency of as much as 3,000–4,000 times that of morphine. The most common use of etorphine has been to capture wild animals and restrain zoo animals. Like carfentanil, the high potency allow it to be used in the field by administration via small volumes in a projectile dart. As little as 8–10 mg or less (total dose) can bring down a full-grown African elephant. It is usually reversed with the antagonist, diprenorphine (M 50–50). Because of the high potency of etorphine, it should only be used by trained and experienced individuals who are aware of the risks.

After IM injection, the action of etorphine is prompt, within 20 minutes. The animals may then be easily restrained or brought to lateral recumbency. If the action is not antagonized, the immobilized state usually persists from 30 to 60 minutes. Used by itself in exotic species, the IM doses of etorphine that usually result in rapid immobilization, sedation, and analgesia are listed in Table 13.13. For most hoofed zoo animals, the dose is approximately 1–2 mg (total dose). For example, a zebra requires about 1.5 mg and the rhinoceros 1–1.5 mg (total dose).

For some animals, etorphine has been combined with the α_2-agonist xylazine. Hyaluronidase (150 IU) has also been added to etorphine and etorphine/xylazine mixtures to increase the absorption rate.

Etorphine or carfentanil should not be used in animals intended for food. There are restrictions on using such immobilizing agents near the hunting seasons. Currently, the only opioids marketed in the United States for use in food-producing species are carfentanil and naltrexone, which are labeled for use in Cervidae. Carfentanil and naltrexone should not be administered within 30 and 45 days, respectively, of a hunting season.

Table 13.13 Doses of etorphine in animals for immobilization

Family	Dose (mg/45 kg or 100 pounds)
Equidae (Mongolian horse, zebra)	0.44
Ursidae (black, grizzly, polar bear)	0.5
Cervidae (fallow deer, moose)	0.98
Bovidae (antelope, bighorn sheep)	0.09

Safe use of etorphine and carfentanil require special precautions. Carfentanil or etorphine should never be used without an antagonist available (such as naltrexone) or be handled without training and experience. These are lipophilic drugs and there is the potential for exposure to lethal doses from skin contact and transdermal absorption. The lethal dose of etorphine for adult humans is small – only 30–120 μg (0.03–0.12 mg) total dose; therefore, accidental injection requires prompt emergency treatment.

Accidental injections of small amounts of etorphine–acepromazine have led to serious respiratory depression, coma, and death in people. In the event of an accidental injection of etorphine, administration of naloxone (0.8 mg) is necessary, to be repeated at 5-minute intervals if symptoms are not reversed. Naloxone, rather than diprenorphine should be used for reversal.

Propoxyphene

Propoxyphene is a methadone congener, which is considered to possess less analgesic activity than codeine but can cause marked respiratory depression. Due to the low efficacy of propoxyphene its use in veterinary medicine is not recommended.

Apomorphine

Apomorphine is a morphine degradation product, but its primary pharmacological effects are not due to the opioid receptor system. Apomorphine primarily acts as a dopamine (D2) agonist. The dopaminergic effects have been used to treat neurodegenerative diseases in people. In Parkinson's disease there is a deficiency of dopamine, and apomorphine's dopaminergic effects can be helpful. A sublingual formulation is also used to treat erectile dysfunction in men.

Through its dopaminergic effects, apomorphine will reliably induce vomiting in dogs. It is used to treat poisoning in dogs if administered shortly after a dog has ingested a poison. It is not as effective as an emetic in cats, which illustrates the interspecies differences in distribution and response of opiate receptors. (In cats, xylazine, an α_2-agonist, is a more reliable emetic.)

Apomorphine's action is presumably via direct stimulation of the chemoreceptor trigger zone (CRTZ) in the area postrema (Mitchelson, 1992). Alternatively, it acts as a dopamine (D_2) agonist, which is a neurotransmitter in both the CRTZ and vomiting center. At high concentrations it acts as an *antiemetic,* presumably via action on central opiate μ-receptors (Scherkl et al., 1990). Naloxone increases, rather than decrease, the emetic effects because naloxone blocks the μ-receptor-mediated antiemetic effects. The route of administration can also influence the effect. Rapid increases in blood concentrations, such as from IV or rapid IM absorption, can produce antiemetic effects by opposing the emetic action in the CRTZ. This explains why lower concentrations produced by SC and mucosal administration may be more effective for producing emesis.

The dose used in dogs has covered a wide range, with the ED_{95} reported to be 0.02 mg/kg IV to 4 mg/kg orally. The most reliable doses listed in review papers are 0.1 mg/kg SC or 0.05 mg/kg IV. After IV injection of 0.03–0.1 mg/kg it produces vomiting reliably in dogs. However, it was more effective if administered SC than if given IM, probably because of rates of absorption as mentioned above (Scherkl et al., 1990). In these studies, doses of 0.04 and 0.1 mg/kg were studied. Alternatively, a 6-mg tablet of apomorphine hydrochloride can be mixed with sterile water or saline solution. A few drops of this solution can be placed in the conjunctival sac. When vomiting occurs, the solution should be promptly rinsed out of the eye. The pH of this hydrochloride solution is low, so it can be irritating to the ocular membranes if not rinsed. Emesis was successfully induced with apomorphine in 100% of dogs at a dose of 0.03 mg/kg IV once, or in 91% of dogs when a crushed tablet dissolved in saline solution was administered to the conjunctival sac (Khan et al., 2012).

The half-life of apomorphine in dogs is 48 minutes after IV injection and it is highly absorbed from IM and SC injection (Scherkl et al., 1990). Apomorphine is much less active orally because of high first-pass metabolism. Adverse effects are attributed to the dopaminergic effects (e.g., hypotension, drowsiness, dyskinesia).

Apomorphine hydrochloride can be obtained from some sources as a 6-mg tablet, or a 2-ml ampule (Apokyn) at a concentration of 10 mg/ml for IV, SC, or IM use. For people, a 3-ml cartridge (10 mg/ml, Apokyn) injectable formulation is administered SC – usually 2 to 6 mg per injection – to treat episodes of severe Parkinson's disease (to be coadministered with an antiemetic) (Lees, 1993).

Partial and Mixed Receptor Opioids

Buprenorphine

Buprenorphine is a high-affinity partial agonist at the μ-opioid receptor, but an antagonist for the κ-receptor (Johnson et al., 2005). Its effects on analgesia, sedation, euphoria, gastrointestinal effects, and respiratory depression are attributed to the μ-opioid receptor activity. Buprenorphine exhibits a ceiling to its analgesic and respiratory depressant effects, in which increased doses do not produce a greater increase in response. It also appears to have a higher safety profile than full μ-receptor agonists. For example the ratio of LD_{50} to ED_{50} – a measure of the therapeutic index – is 464 for morphine, but up to 12,313 for buprenorphine. The LD_{50} in dogs is 79 mg/kg, but therapeutic doses usually do not exceed 0.04 mg/kg. In cats, compared to full agonist μ-receptor agonists such as morphine and hydromorphone, it produces less dysphoria, excitement, vomiting, or nausea. It is a Schedule III narcotic (Table 13.2) and has less potential for abuse than pure μ-opioid receptor agonists. There are formulations available for use in people that are used for treatment of opiate addiction.

The cardiovascular safety of buprenorphine has been evaluated in dogs and horses (Carregaro et al., 2006; Martinez et al., 1997). The changes observed were not important enough to produce clinical significance.

Because buprenorphine is a μ-opioid receptor partial agonist, and a κ-receptor antagonist, there is concern that it may inhibit the effects of coadministered opioids. Although theoretically it is possible that buprenorphine could antagonize the antinociceptive effects of other opioids, there is no clinical evidence of this property. In laboratory animals, preadministration of buprenorphine did not cause impairment of μ-receptor acceptability beyond the duration of antinociceptive activity (Englberger et al., 2006). Nevertheless, buprenorphine binds to the μ-opioid receptor with higher affinity than other opioids. It will displace other opioids to elicit a withdrawal response in individuals with opioid dependence. Because of the high receptor affinity, it will require a much higher dose of naloxone to reverse respiratory depression and other opioid effects compared to doses used to reverse effects from morphine.

The high affinity of buprenorphine for the μ-opiate receptor may induce a longer duration of pain control in animals. This duration of analgesia in cats has been reported to be less than 4 hours (Taylor and Houlton, 1984; Robertson et al., 2005b; Stanway et al., 2002), up to 5 hours (Johnson et al., 2007), and perhaps as long as 8 hours. In dogs, the analgesic effects were not much longer than the effects from morphine (Brodbelt et al., 1997). The potency of buprenorphine is approximately 25 times that of morphine (Table 13.8). In some of the clinical studies of buprenorphine in humans it had comparable efficacy to that of morphine. In animals, the efficacy of buprenorphine has been evaluated in some veterinary studies of surgical pain – primarily in cats. It was more effective than morphine in cats (Stanway et al., 2002), more effective than oxymorphone or ketoprofen (Dobbins et al., 2002), and equally effective as butorphanol (Johnson et al., 2007). When administered subcutaneously in cats (0.02 mg/kg) it produced a minimum antinociceptive effect in comparison to morphine or methadone, but the route of administration may have limited its effect (Steagall et al., 2006). It was equally effective as morphine in dogs in postoperative orthopedic surgery (Taylor and Houlton, 1984) and similarly as effective as transdermal fentanyl solution in postoperative soft tissue and orthopedic dogs (Linton et al., 2012). It is, at minimum, effective for treatment of mild to moderate pain and perhaps effective for more severe pain. In most of the studies in which the analgesic effects have been evaluated, a range of doses of 10 μg/kg (0.01 mg/kg) to 40 μg/kg have been used in dogs, cats, and horses, which is higher than doses used in people (4–8 μg/kg). However, as stated previously, results of clinical and research studies have varied.

The oral bioavailability of buprenorphine is low because of rapid clearance and first-pass metabolism. Buprenorphine has high lipophilicity (Table 13.6) and lipophilicity is increased at a pH higher than its pKa of 8.3. It has a large volume of distribution (greater than 7 l/kg) and high brain to plasma tissue ratios. Buprenorphine is highly protein bound in whole blood. In dogs, buprenorphine glucuronide conjugates appear to be the primary metabolites, which are eliminated via biliary secretion. Studies suggest some of the glucuronide conjugates of buprenorphine and norbuprenorphine may provide analgesic effects (Brown et al., 2011). The metabolism of buprenorphine in cats has not been reported.

Similar to other opioids, clinically relevant cardiovascular changes are minimal but increases in total peripheral resistance can occur. Buprenorphine is well tolerated in dogs and cats with sedation, mydriasis (cats), and euphoria occurring as adverse effects. Nausea and vomiting are possible, but occur rarely with buprenorphine. Excitement in horses after doses of 5 and 10 μg/kg IV have been observed (Carregaro et al., 2007), which was characterized as head-nodding, shifting, trotting, and restlessness. Excitement may be less in horses that have clinical pain.

Despite the lipophilicity of buprenorphine the onset of effect appears to be delayed following IV administration. Initially the lag in effect was thought to be due to slow binding to the opiate receptors, but studies in rats indicate the distribution into the CNS may be the rate-limiting step (Yassen et al., 2005). The effect of buprenorphine may also last longer than the plasma concentrations because of the slow diffusion out of the CNS and high affinity for the μ-opioid receptors.

The oral mucosal (buccal, sublingual) administration had high bioavailability (>100%) in one study (Robertson et al., 2003, 2005b), but follow-up studies showed that this value may have been biased. Lower absorption of approximately 30% was shown by Hedges et al. (2014) and they attributed this difference to the method of blood collection. When blood samples were collected from the jugular vein, it artificially increased the concentrations measured because of the anatomic proximity of the jugular vein to the oral mucosal venous drainage. The lower absorption from transmucosal administration to cats was also apparent in the analgesic response as measured by thermal threshold (Hedges et al., 2014). Cats administered oral mucosal buprenorphine (20 μg/kg) had increases in thermal threshold, but it was transient and of limited magnitude compared to the IV dose.

Oral mucosal absorption in dogs has been reported to be 38%, but this also may be overestimated as blood samples were obtained from the jugular vein, which directly drains from the site of administration, and, clinically, rescue analgesia was more frequent and was needed sooner unless a high (120 μg/kg) transmucosal dose was administered (Abbo et al., 2008; Ko et al., 2011). The oral transmucosal bioavailability is low in horses and the bias of jugular sampling overestimating buprenorphine plasma concentrations was documented in horses, as in cats (Messenger et al., 2011). In humans, there are sublingual tablets used primarily for treatment of opiate addiction. The sublingual absorption in humans is approximately 30%.

Buprenorphine has been extensively studied in cats. Steagall et al. (2014) reviewed these studies and readers are referred to that paper for greater detail. Important conclusions from Steagall et al. (2014) can be summarized here. Buprenorphine has a delayed onset of action in cats, and exerts moderate analgesic effects, with the duration of action shorter than suggested in other papers (e.g., 4-hour duration rather than 8-hour duration). Low doses of 20 μg/kg subcutaneously are not recommended because of low absorption and poor efficacy. The IV or IM dose is more effective and doses of 20 μg/kg or higher are recommended. The oral mucosal dose should be increased (40 μg/kg) to overcome low bioavailability. Overall, the clinical trials have demonstrated that analgesic effects in cats are inconsistent and difficult to compare because of different methods of pain evaluation, surgical procedures, dose, and route of administration. Although it is often assumed to be effective, these authors concluded that effects are inconsistent and "buprenorphine may not provide sufficient analgesia in some cats". It is also observed that the only veterinary approved product for cats (Simbadol^{TM}, 1.8 mg/ml) is administered to cats at a dose of 0.24 mg/kg SC (240 μg/kg) once daily. This dose was shown to be safe and effective in clinical trials, but it is much higher dose than used in earlier studies.

Oral (per os) bioavailability of buprenorphine is low (9.7%) and variable in rats, and less than 10% in people. In rats it was not effective by oral administration until high dosages (≥5 mg/kg PO) are administered (Martin et al., 2001; Brewster et al., 1981). The dose resulting in analgesia (5 mg/kg) was not voluntarily eaten in gelatin by the rats and needed to be administered via gavage.

Transdermal absorption of buprenorphine has been reported in dogs after application of the patch approved in Europe. A slow absorption occurred with a mean T_{MAX} of 55 hours and C_{MAX} of 2 ng/ml after applying a 52.5-μg/h patch to 12.7 kg Beagles (Pieper et al., 2011). In cats weighing 5.1–7.4 kg, a 35-μg/h transdermal patch resulted in a slow increase in plasma buprenorphine concentration until the patch was removed at 72 hours, with a mean buprenorphine concentration of 4.24 ng/ml (Murrell et al., 2007). The pharmacokinetics of transdermal buprenorphine patches have not been reported in horses.

Buprenorphine hydrochloride is available in Europe as a veterinary formulation (Vetergesic). In the USA, the human formulation is commonly used (Buprenex, 0.3 mg/ml) and a formulation is specifically approved for cats in a once-daily subcutaneous formulation (Simbadol, 1.8 mg/ml). There are numerous other formulations approved for human use including sublingual tablets, transdermal patches, buccal film, and sublingual films to treat opiate addiction. Dose recommendations for buprenorphine use in animals are presented in Table 13.14.

Table 13.14 Buprenorphine dosages

	IV / IM / SC	Oral transmucosal
Dog	0.01–0.04 mg/kg q 4–8 h	0.12 mg/kg q 8 h (low absorption and impractical; therefore not recommended)
Cat	0.01–0.02 mg/kg q 4–8 h (SC not recommended at these doses) 0.24 mg/kg SC, q 24 h, for 3 days (use 1.8 mg/ml Simbadol formulation).	0.02–0.04 mg/kg q 4–12 h
Horse	0.005–0.01 mg/kg	NR
Rat / mouse	0.05–0.1 mg/kg q 4–12 h	NR
Guinea pig / hamster	0.05–0.1 mg/kg 4–12 h	NR
Rabbit	0.01–0.05 mg/kg q 4–12 h	NR
Primates	0.005–0.01 mg/kg q 4–12 h	NR
Ferrets	0.01–0.03 mg/kg q 4–12 h	NR

NR, not recommended.

Butorphanol

Butorphanol is a κ-opiate receptor agonist and either a partial agonist or antagonist at the μ–opiate receptor depending on the study. The potency is often reported to be five to seven times that of morphine, but unpublished data by the author (BK) indicates butorphanol is closer to equipotent with morphine in dogs (Table 13.8). The efficacy of butorphanol is dose dependent, but plateaus with efficacy limited to mild and moderate pain. Butorphanol is a commonly used analgesics and anesthetic adjuncts in veterinary medicine.

Butorphanol is a weak base with a pKa of 10.7, and is highly lipophilic with a Log P (octanol : water) of 3.3 (Table 13.6). Preparations of butorphanol are available commercially as butorphanol tartrate. One mg of butorphanol tartrate is equivalent to 0.68 mg of butorphanol base. The commercially available injectable preparation (Torbugesic, Torbutrol, Stadol) is available in 0.5, 2, and 10 mg of butorphanol (base)/ml in a buffered solution (pH of 3.5 to 5.5). Tablets (Torbutrol) are available as 1, 5, and 10 mg of butorphanol (base).

Butorphanol has been commonly used in cats with a dose range of 0.1 to 0.8 mg/kg. Above 0.8 mg/kg there is a ceiling effect and no further beneficial effects occur with higher doses. The duration of effect is reportedly not increased with higher doses (Sawyer et al., 1991; Lascelles and Robertson, 2004). Routes of administration include intramuscular, intravenous, subcutaneous, and oral. Pharmacokinetics are listed in Table 13.5. The comparison of clearance and terminal half-life between dogs and cats indicates substantially slower elimination in cats compared to dogs.

Compared to less lipophilic opioids such as hydromorphone, butorphanol is reported to have a faster onset of effect (Lascelles and Robertson, 2004), although in other studies the onset was longer (Johnson et al., 2007). The duration of antinociceptive activity of butorphanol is variable, depending on the report. It has generally been 3 hours or less in most studies (Lascelles and Robertson, 2004; Sawyer and Rech, 1987), and from less than an hour to 1.5 hours in dogs (Grimm et al., 2000; Sawyer et al., 1991). In a review of several studies spanning a 20-year period in cats (Wells et al., 2008), the mean duration of analgesia for all dosages and routes was 160.3 minutes with a standard deviation of ± 130.8 min. The mean dosage administered was 0.4 mg/kg. The effective plasma concentration was above 45 ng/ml from the analysis of these studies, which is maintained for approximately 3 hours at a dose of 0.4 mg/kg.

Butorphanol is effective as an antitussive when administered per os to dogs (Gingerich et al., 1983) and cats, but due to its poor bioavailability, it is not an effective analgesic unless high doses are administered (1–2 mg/kg PO q 2–4 h). The sedative effects of butorphanol are prominent and appear to occur at lower dosages than its analgesic effects. Therefore sedation following butorphanol administration should not be interpreted as analgesia (Sawyer et al., 1991). Butorphanol was previously unscheduled because of lower abuse potential compared to full μ-receptor agonists, but it is now a DEA Schedule IV drug (Table 13.2).

Butorphanol, like other opioids, causes minimal clinically relevant cardiovascular effects when administered at recommended dosages. Adverse effects are similar to other opioids including sedation, dysphoria, mydriasis (cats), decreased GI motility, and constipation. Intramuscular and subcutaneous administration is painful. The respiratory depressant effects of butorphanol appear to be less than that of opioid agonists. Interestingly, the LD_{50} of IV butorphanol in dogs, 10 mg/kg, is markedly less than pure μ-agonists including morphine HCl (175 mg/kg IV), methadone HCl (28.7 mg/kg IV), and codeine phosphate (97.8 mg/kg IV) (Kasé et al., 1959).

In horses, butorphanol has been favored over other opioids because it appears to be better tolerated. Excitatory effects, although possible, are less than with other opiates because these effects are primarily mediated via the μ-opioid receptor (see Section Central Nervous System Excitation). Decreased fecal output was observed in horses (Sellon et al., 2001, 2004), but it was transient and not as severe as with other opioids. Less severe inhibition of gastrointestinal motility in horses are probably attributed to less stimulation of the μ-opioid receptor by butorphanol (see Section Gastrointestinal Effects; DeHaven-Hudkins et al., 2008).

Doses used in horses for treatment of visceral pain are in the range of 0.1 or 0.2 mg/kg IV as a bolus. After a bolus injection, ataxia, increased locomotor activity, and decreased intestinal motility may occur. In horses, the duration of effectiveness from a single dose is short – 30 to 90 minutes – in most studies. Therefore, to maintain analgesia without producing high peak concentrations that occur with intermittent boluses, a constant dose infusion protocol has been developed by Sellon et al. (2001, 2004). In those studies the half-life in horses was short (44 minutes) and the clearance was rapid (21 ml/kg/min). To maintain a plasma concentration in the effective range (judged to be 20–30 ng/ml) a loading dose of 18 μg/kg followed by a constant rate infusion of 24 μg/kg/h was used. This treatment was well tolerated with few adverse cardiovascular effects, and less adverse effects on intestinal motility than bolus doses. Some ataxia still occurred. In a follow-up study (Sellon et al., 2004), a lower infusion dose of 13 μg/kg/h was administered to patients that had undergone abdominal surgery. These horses had decreased fecal output, but it was only transient. There was less pain in treated horses, recovery from surgery was faster, and hospitalization time was less.

Nalbuphine

Nalbuphine is a κ agonist and μ receptor antagonist with similar pharmacological effects as butorphanol. Nalbuphine is effective for mild to moderate pain and appears to be well tolerated in dogs and cats although it has not been extensively investigated. Very few studies have investigated nalbuphine in horses, but effects and adverse effects are expected to be similar to morphine and butorphanol. An advantage of nalbuphine over butorphanol is that nalbuphine is not currently a DEA scheduled drug, therefore special record keeping is not necessary. Nalbuphine exhibits similar potency and pharmacokinetics as morphine, therefore dosage recommendations are the same as for morphine. Nalbuphine can be administered to antagonize the respiratory depressant effects of opioid agonists, but maintain some degree of analgesia.

Pentazocine

Pentazocine is a κ agonist and μ receptor partial agonist with similar pharmacological effects as butorphanol and nalbuphine. Pentazocine is effective for mild to moderate pain with a 1–3 hour duration of effect. Pentazocine may cause less sedation as compared to other opioids, but similar to other opioids it can cause excitement and tremors at high doses. Pentazocine (Talwin) was once commonly used in horses, but is now rarely used. The indication approved by the FDA for horses is 0.33 mg/kg once daily IV or IM for treatment of colic pain (repeated if necessary in 10–15 minutes). The approved use in dogs was 1.67 to 3.3 mg/kg IM for treatment of postoperative pain.

Nalorphine

Nalorphine is a partial κ agonist and μ receptor antagonist which exhibits minimal analgesic effects. The efficacy of reversing opioid agonist induced respiratory depression is variable and can exacerbate it in some cases. Therefore the use of nalorphine is not recommended.

Opioid Antagonists

The primary indication for opioid antagonists is for the treatment of an opioid agonist overdose if severe respiratory depression is present or reversal of adverse effects such as severe dysphoria. The duration of antagonist effect is often shorter than that of the agonist and repeated doses are typically required. Opioid antagonists must be used extremely cautiously in animals that are painful as administration can result in acute exacerbation of pain leading to cardiovascular shock and even death. Nalbuphine and butorphanol can also be used to reverse the respiratory depressant effects of opioid agonists while maintaining some analgesia. Opioid antagonists not only reverse exogenously administered opioids, but also endogenous opioid peptides. Opioid antagonists are effective in controlling crib biting in horses, but due to the need for parenteral administration and efficacy limited to 6 hours or less, are not clinically useful. Although research suggests ultralow doses of opioid antagonists may enhance analgesic effects of μ-opioid agonist (La Vincente et al., 2008), the clinical application has not been defined and is currently not recommended until further research in animals is completed.

Naloxone

Naloxone is an opioid antagonist with greater activity at the μ receptor compared to the κ and δ receptors. Naloxone also interacts at the GABA receptor as an antagonist and as a result can elicit seizures upon administration. Naloxone is typically administered 0.01–0.04 mg/kg IV and repeated as needed every 2–3 minutes to reverse respiratory depression. Careful titration can reverse the respiratory depressant and other adverse effects of an opioid agonist while maintaining some degree of analgesia. To achieve the desired effect during titration the full dose of 0.04 mg/kg should not be administered initially. Instead, start with 0.04 mg/ml solution and administer increments of 1 ml every 30 seconds until vocalization or signs of dysphoria stop. A dose of 0.01 mg/kg IV has been given for this purpose without losing analgesic effects. A dose of 1 ml (0.4 mg) will reverse 1.5 mg oxymorphone, 15 mg morphine, 100 mg meperidine, and 0.4 mg fentanyl.

Naltrexone

Naltrexone is an opioid antagonist with activity at the μ, κ, and δ receptors. Naltrexone is most commonly used to reverse carfentanil administered at a dose of 100 mg naltrexone for 1 mg carfentanil, with one-quarter of the dose administered IV and the remaining three-quarters administered SC.

Nalmefene

Nalmefene is an opioid antagonist with greater activity at the μ receptor compared to the κ and δ receptors, similar to naloxone. However, the duration of effect is longer than that of naloxone. Nalmefene administered at 0.012 mg/kg/h was as efficacious as naloxone 0.048 mg/kg/h in antagonizing the respiratory depressant effects of fentanyl administered to dogs (Veng-Pedersen et al., 1995).

Diprenorphine

Diprenorphine (M 50/50) is an antagonist at the μ, κ, and δ receptors, similar to naltrexone. Diprenorphine is used primarily to reverse the effects of etorphine. Two milligrams of diprenorphine will reverse the effects of 1 mg etorphine.

Newer Agents

Newer antagonists are being explored for use, primarily to limit the adverse effects of opioids on gastrointestinal motility. These agents are considered *peripheral* opioid antagonists, rather than *central* opioid antagonists. Such agents include alvimopan and methylnaltrexone. They are being investigated to be used as therapeutic agents to treat gastrointestinal motility problems associated with opioid analgesic use as well as other stress or pain syndromes that cause a decrease in gastrointestinal motility (for example postoperative ileus) (DeHaven-Hudkins et al., 2008). These agents are capable of restoring gastrointestinal motility, but preserving opioid-mediated analgesia. Alvimopan has advantages over methylnaltrexone with respect to potency and duration of activity. These antagonists are discussed in more detail in Chapter 46.

Other Central Analgesic Drugs

Tramadol

Tramadol is a centrally acting analgesic eliciting it effects through a complex interaction as a μ-opiate agonist (by an active metabolite) and as serotonin (5-HT) reuptake inhibitor, noradrenergic reuptake inhibitor (α-2), and muscarinic (M1) antagonist. Tramadol is both highly lipophilic (Log P 2.5) and highly soluble (33 mg/ml), making it suitable for oral and IV administration. (There is no IV formulation commercially available in the USA at this time.)

Tramadol is administered as a racemic mixture (+ and −). It is metabolized to greater than 30 metabolites, with perhaps as many as 11 metabolites significant. The most important metabolite, with respect to pharmacological activity is the active metabolite, O-desmethyltramadol (also referred to as the M1 metabolite), which is metabolized by the CYP2D isoenzyme in many species. Concurrent administration of a CYP2D inhibitor (quinidine, fluoxetine, paroxetine, or sertraline) with tramadol significantly decreases the analgesic effects following tramadol administration. Additionally, CYP2D poor metabolizers (human) have poorly controlled pain in response to tramadol administration.

Tramadol's pharmacological effects are complex. The effects can be attributed both the (+) and (−) isomer. Tramadol (+) is a μ-opiate agonist (weak) and also inhibits serotonin (5-HT) uptake at the synapse. Tramadol (−) inhibits norepinephrine reuptake and can produce analgesic activity via α_2-receptors. The metabolite *O*-desmethyltramadol (M1) (+) is a μ-opiate agonist with potency of 200–300 times tramadol. Taken together, the effects of tramadol may accomplish *multimodal analgesia* via these mechanisms. All three mechanisms described can produce analgesia, sedation, and other pharmacological effects, but because deficiencies in metabolism to the M1 metabolite diminish analgesia in people (discussed below), the opiate-related effects of this metabolite are regarded as an important contribution to the efficacy.

Tramadol is used for mild to moderate pain in humans and its use is extrapolated to veterinary species. Sedation, nausea, and vomiting are adverse effects that may be attributed to tramadol administration. Tramadol has less effect on gastrointestinal motility compared to opioid drugs. High doses of tramadol may lower the seizure threshold; therefore, repeated high doses should be avoided in patients prone to seizures such as epileptics. Intravenous administration of *O*-desmethyltramadol to healthy dogs resulted in sedation whereas IV tramadol did not (KuKanich and Papich, 2004b). Tramadol may produce inhibition of the reuptake of serotonin in veterinary species (although this has not been confirmed). Nevertheless, concurrent administration of tramadol and other drugs that act through serotonergic mechanisms (tricyclic antidepressant, selective serotonin reuptake inhibitor, serotonin–norepinephrine reuptake inhibitor or meperidine) should be avoided because of a potential for serotonin syndrome (Mohammad-Zadeh et al., 2008).

In dogs, tramadol is rapidly metabolized following oral and IV administration, primarily to the inactive metabolite *N*-desmethyltramadol with only low concentrations of *O*-desmethyltramadol measured in the plasma (Matthiesen et al., 1998; Giorgi et al., 2009; KuKanich and Papich, 2011). The half-life of tramadol following IV and oral administration is 0.8 and 1.7 hours, respectively (Table 13.15). The half-life of *O*-desmethyltramadol is 1–2 hours following oral tramadol administration. The oral bioavailability of tramadol in fasted dogs was initial reported to be 65 ± 38%, but a recent study reported it as low as 4 ± 3% (Black et al., 2013). A population pharmacokinetic study in postoperative dogs demonstrated highly variable plasma tramadol concentration with a predicted C_{MAX} range of 47–613 ng/ml after the second dose and very low concentrations of the active metabolite M1 (Benitez et al., 2015a). Based on these data, single doses or short term administration results in unpredictable drug exposure in dogs. Decreased bioavailability occurs with repeated administration to dogs with the

Table 13.15 Tramadol pharmacokinetics in animals compared to people. References: KuKanich and Papich, 2004b; Papich and Bledsoe, 2007; Pypendop et al., 2009; Black et al., 2013; Grond and Sablotzki, 2004.

[a] All of the O-desmethyltramadol (M1) pharmacokinetic parameters were derived from administration of tramadol as the parent drug.

relative bioavailability decreasing at day 7 to approximately 18% compared to the first dose (Matthiesen et al., 1998) suggestive that tramadol dosages would have to be substantially increased over time to maintain targeted drug exposure. Decreased bioavailability with multiple doses has not been reported in other veterinary species.

Human poor metabolizers of tramadol to *O*-desmethyltramadol (similar metabolism profile to dogs) had 60–80% failure rates to tramadol for postoperative pain compared to 20–30% failure rates in humans who had adequate conversion of tramadol to *O*-desmethyltramadol (Stamer et al., 2007). Consistent efficacy of tramadol in dogs has not been adequately demonstrated. Oral tramadol, 10 mg/kg, resulted in increases in mechanical thresholds in laboratory Greyhound dogs (KuKanich and Papich, 2011). However, IV tramadol at doses up to 10 mg/kg failed to affect thermal thresholds in laboratory Beagle dogs (Kögel et al., 2014). A placebo-controlled clinical trial in dogs with osteoarthritis resulted in tramadol treated dogs resulted in improved mobility by owner questionnaire, but because of high variability, failed to achieve an adequate statistical power (Malek et al., 2012). Plasma tramadol concentrations were not detected in four of the dogs after 2 weeks of therapy after 4 mg/kg PO q 8 h, and the mean concentrations were very low, indicative of induced metabolism. The low to undetectable concentrations of the active drug in these studies did not support the use of tramadol for osteoarthritis in dogs at 4 mg/kg PO q 8 h. The current dose recommendation for tramadol use in dogs is 3–5 mg/kg PO q 6–8 h, but doses up to 10 mg/kg have been administered, especially when tramadol metabolism is increased because of repeated exposure. Overall, despite the interest among clinicians for its use, there are very few data from well-designed controlled studies (either experimental or clinical) to support the administration of tramadol in dogs to treat painful conditions. Some studies that demonstrated efficacy, used current administration of a NSAID, making it difficult to evaluate the true effectiveness of tramadol (Flôr et al., 2013; Davila et al., 2013).

The efficacy of tramadol as an analgesic in cats has been reported in experimental models in which dose-dependent increases in analgesia occurred following oral tramadol 0.5–4 mg/kg (Pypendop et al., 2009). Tramadol administered to postoperative ovariohysterectomy cats required less rescue analgesia than placebo-treated cats, but cats treated with the combination of tramadol (2 mg/kg SC q 8 h) and the NSAID vedaprofen did not require any rescue analgesia (Brondani et al., 2009).

There are important differences between cats and dogs (Table 13.15). In cats there is a slower clearance and a longer half-life compared to dogs. Most importantly, the clearance of the *O*-desmethyltramadol metabolite (M1), which is conjugated to glucuronic acid for elimination in other animals, is much slower in cats. Because the clearance of M1 is slower in cats than in dogs, the ratio of M1 to tramadol is 1 : 1 or higher in cats (Table 13.15). The M1 metabolite is associated with greater opiate-mediated effects than the parent drug, therefore effects attributed to opiates are observed more often in cats than dogs. Because of the increased effects in cats, the doses should be lower than in dogs.

In anesthetized cats, tramadol at a dose of 4 mg/kg IV produced a dose-dependent respiratory depression, which was partially reversed by naloxone (Teppema, 2003). Tramadol has also demonstrated efficacy as an antitussive agent in cats, which may be attributed to the M1 metabolite (Nosal'ova et al., 1991; Pypendop and Ilkiw, 2008). Doses of 4–5 mg/kg orally produce some euphoria to dysphoria and mydriasis in experimental cats (Papich and Bledsoe, 2007; Pypendop and Ilkiw, 2008). Dose recommendations for cats have been in a range of 2–4 mg/kg PO q 8–12 h, but further work is necessary to determine the optimum dose and frequency. Oral tramadol is notoriously unpalatable in cats and causes salivation and resistance to medicate; therefore, repeated administration can be challenging.

The pharmacokinetics and metabolism of tramadol in horses is quite variable. Tramadol IV is rapidly eliminated (half-life 1–2 hours) with low concentrations of M1 measured (Stewart et al., 2011; Giorgi et al., 2007). The oral bioavailability of the immediate release formulations were relatively high in one study 60–70% (Girogi et al., 2007), but low (~10%) in another (Stewart et al., 2011). The plasma concentrations of M1 are also quite variable between studies after PO tramadol and may be due to differences in conjugation of M1 (Guedes et al., 2014). Multiple doses of oral tramadol at 10 mg/kg q 12 h produced plasma tramadol concentrations within a potential therapeutic range in horse, but M1 concentrations were relatively low (Guedes et al., 2014). Tramadol was well tolerated at 10 mg/kg PO q 12 h for 5 days based on behavior, blood pressure measurements, heart rate respiratory rate, and gut sounds. However, the horses objected to oral tramadol administration, which may be due to the bitter taste of tramadol. One horse developed colic on day 4 of the study, which resolved after skipping one dose and with periodic walking and it is not clear if that was directly due to tramadol or the stresses of the study. The horse was administered the remaining doses of tramadol and finished the study without further adverse effects. Horses with chronic laminitis administered oral tramadol 10 mg/kg q 12 h for 7 days had significant improvement in forelimb off-loading and achieved reasonable tramadol and M1 maximum plasma concentrations with no adverse effects reported (Guedes et al., 2016). Therefore, oral tramadol may have some use as an analgesic in horses, but the efficacy may be dependent on an individual animal's plasma M1 concentrations, which are variable.

Tramadol (Ultram, and generic) is available in 50-mg tablets. An extended release tablet (Ultram-ER) also has been examined in dogs (Papich et al., 2007). A single 300-mg tablet produces sustained plasma concentrations in dogs in excess of 24 hours but the concentrations of the extended release tablet were much lower than comparable doses used in people. There are no commercially available injectable formulations in the USA, but are available in some other countries.

Other Routes of Administration

In order to maximize analgesic effects and minimize adverse effects, other routes of opioid administration have been evaluated. The two routes most commonly utilized are epidural and synovial administration.

Epidural

Opioids administered by the epidural route interact with spinal opiate receptors to elicit an analgesic response. Epidural opioid administration does result in systemic absorption of the opioid, but at lower concentrations than parenteral administration because the total dose (mg/kg) is lower. However, the high spinal concentrations achieve profound spinal analgesia. Because of their lipophilicity, some opioids can diffuse from the epidural space to the plasma. The high lipophilicity of sufentanil and alfentanil (and presumably fentanyl) also result in a more rapid effect (and shorter duration) than epidural morphine (Tiseo et al., 1990). Morphine is the most common opioid administered by the epidural route and has produced a duration of effect up to 24 hours. Epidural administration results in decreased systemic adverse effects such as sedation and dysphoria, but other adverse effects such as pruritus, urine retention, and constipation can still occur. The efficacy is probably due to the very high concentrations of morphine interacting with the spinal receptors. Preservative-free morphine solutions are available for epidural administration as the preservatives (such as phenol and formaldehyde) can cause toxicity and adverse effects if administered for multiple doses. However, some experts state a single dose of preservative-containing solutions have been administered to dogs. Techniques for administering opioids via this route in veterinary species are provided in more detail in other chapters (Skarda and Tranquilli, 2007).

Peripheral

Opiate receptors have been identified in the synovial membranes of various species including the horse and dog (Sheehy et al., 2001; Keates et al., 1999). Intaarticular administration of morphine following endoscopic procedures produces a significant analgesic effect as compared to a placebo in humans (Lawrence et al., 1992). Low plasma concentrations are attained following intraarticular administration presumably resulting in fewer adverse effects. Dose titration studies or placebo controlled studies of intraarticular morphine in horses have not been reported. Intraarticular morphine 0.1 mg/kg diluted to a volume 0.5 ml/kg appears to decrease the need for supplemental analgesia following stifle surgery in dogs (Sammarco et al., 1996). Other techniques for local administration of opioids are provided in more detail in other texts (Skarda and Tranquilli, 2007).

The Use of Opioids in Nonmammalian Vertebrates

The pharmacology of opioids in nonmammal species is not as abundant as for the domestic mammal species, but opioid receptors are apparently highly conserved among groups of vertebrates (mammals, birds,

Table 13.16 Relative supraspinal opiate receptor density in different species

	μ	κ	δ
Frog brain	37%	19%	44%
Chicken forebrain	58%	25%	17%
Pigeon brain	14%	76%	10%
Junco (passerine) brain	74%	22%	4%
Rat forebrain	41%	9%	50%
Mouse forebrain	25%	13%	62%
Guinea Pig forebrain	25%	50%	25%
Dog cortex	5%	58%	37%
Human cortex	29%	37%	34%

frogs, and fish) (Li et al., 1996). μ, κ, and δ opiate receptors have been identified in birds' brains as high affinity, but appear to be low in density as compared to mammals. The relative density of opioid receptors also appears to be dependent on the species of bird evaluated (Table 13.16). Therefore a drug and dosage effective in parrots may or may not be effective in doves, finches, waterfowl, ratites, etc. The limited studies available have demonstrated a wide range of doses and effects. Some studies have evaluated the efficacy of opioids in companion birds. Butorphanol (1 mg/kg IM) decreased the MAC of isoflurane in cockatoos, which may be indicative of analgesic effects (Curro et al., 1994). The duration of effect or different doses were not evaluated. In a separate study, butorphanol (1 mg/kg IM) resulted in a greater effect than buprenorphine (0.1 mg/kg IM) in African Grey Parrots (Paul-Murphy et al., 1999). However, only a single dose for each drug was assessed, the birds were evaluated to only 60 minutes, and neither drug was effective in greater than 50% of the animals assessed at 60 minutes. Butorphanol 2 mg/kg IM has no significant effects on electrical nociceptive stimulus in Hispaniolan Amazon parrots (Sladky et al., 2006). Nalbuphine (12.5, 25, 50 mg/kg IM) administered to Hispaniolan Amazon parrots produced significant effects for 1.5–3 hours after administration using a thermal model (Sanchez-Migallon Guzman et al., 2011). Buprenorphine (0.1, 0.3, 0.6 mg/kg IM) resulted in significant antinociceptive effects for at least 6 hours using a thermal model, which were approximately dose proportional in American kestrels (Ceulemans et al., 2014). Butorphanol (1, 3, 6 mg/kg IM) failed to produce significant antinociceptive effects in American kestrels using a thermal model (Guzman et al., 2014a). Tramadol 30 mg/kg PO produced thermal antinociception in Hispaniolan Amazon parrots for up to 6 hours (Sanchez-Migallon Guzman et al., 2012). Tramadol (5, 15, 30 mg/kg PO) resulted in significant antinociceptive effects in American kestrels for up to 9 hours at 5 mg/kg, but the effect was less pronounced at the higher doses (Guzman et al., 2014a).

Table 13.17 The dose required to elicit a 50% maximum analgesic effect (ED_{50}) and lethal dose (LD) of opioids in tree frogs

	ED_{50} (mg/kg)	LD (mg/kg)
Morphine	24.6	ND
Fentanyl	0.47	30
Methadone	6.1	1000
Meperidine	31.7	ND
Buprenorphine	46.4	ND

ND, not determined.

The effects of various opioids have been studied in amphibians (grass frogs). A single study evaluated the antinociceptive effects of morphine, methadone, meperidine, fentanyl, and buprenorphine in an experimental model (Table 13.17). The opioids were administered SC into the dorsal lymph sac. The effective dose to elicit a 50% maximum analgesic response (ED_{50}) was determined as well as the lethal dose (LD) of some of the compounds (Stevens et al., 1994). The analgesic effects lasted for at least 4 hours, which was the last time point evaluated. In turtles, butorphanol did not provide an antinociceptive effect, even when administered at a high dose of 2.8 and 28 mg/kg, but it produced respiratory depression (Sladky et al., 2007). However, in the same turtles, morphine at 1.5 or 6.5 mg/kg produced significant antinociceptive effects. Morphine at these doses caused long-lasting respiratory depression. At these doses the respiratory depression may limit clinical use. Hydromorphone (0.5 mg/kg SC) elicited antinociceptive effects with effects lasting at least 24 hours, but less than 48 hours (Mans et al., 2012). However, in the same study, buprenorphine (0.2 mg/kg SC) did not elicit antinociceptive effects in red-eared slider turtles using a thermal stimulus model. These studies in turtles indicate that the population of opioid receptors may be different in turtles compared to other vertebrates with μ-opioid receptors providing more prominent effects than κ or δ(Sladky, 2009). Tramadol provided significant antinociceptive effects in red-eared sliders using a thermal model at least up to 24 and 96 hours for 5 and 10 mg/kg, respectively (Baker et al., 2011). In contrast to morphine, respiratory depression effects were not observed with tramadol.

Morphine 10 and 20 mg/kg SC resulted in significant antinociception for up to 8 hours in Bearded dragons using a thermal stimulus, but butorphanol did not produce significant effects up to 20 mg/kg IM (Sladky et al., 2008). In contrast, butorphanol 20 mg/kg IM in corn snakes resulted in significant antinociceptive effects to at least 8 hours, but morphine up to 40 mg/kg IM did not result in effects using a thermal model (Sladky et al., 2008).

The analgesic effects of morphine and meperidine were evaluated in crocodiles (Kanui and Hole, 1992).

Morphine, 0.3 mg/kg IP, was the dose that produced the maximum analgesic effect in the experimental model. Morphine, 0.1 mg/kg IP, produced significant analgesic effects from 30 minutes to 2 hours. The analgesic effect following the higher dose, 0.3 mg/kg, would be expected to last longer, but the duration of the higher dose was not assessed. Meperidine produced a maximum response at a 2–4 mg/kg IP dose, and 2 mg/kg IP resulted in significant analgesia from 30 minutes to 3 hours.

The effects of butorphanol, 1 mg/kg IM, on the minimum alveolar concentration of isoflurane were evaluated in green iguanas (Mosley et al., 2003). No significant reduction in the MAC occurred, but only a single dose was assessed. A separate study demonstrated butorphanol, 1 mg/kg, had no significant cardiovascular effects in iguanas when administered to isoflurane-anesthetized animals (Mosley et al., 2004).

The effects of opioids have not been extensively evaluated in fish due to inherent difficulties evaluating pain in fish. Morphine 0.3 mg/g (300 mg/kg) appeared to produce an analgesic response in an experimental rainbow trout model, but the duration of the effect was not evaluated (Sneddon et al., 2003). The metabolism and analgesic effects of morphine in goldfish were evaluated following a bath administration (Jansen and Green, 1970). No metabolites were identified and recovery of unchanged morphine accounted for nearly 100% of the administered dose. A morphine bath consisting of 0.56 mg of morphine per 1000 ml water resulted in maximal inhibition of an electrical stimulus model in 5/5 fish, however tolerance was rapidly noted with repeated exposure every 3 days. Jansen and Green reported apparent CNS excitement with higher doses similar to mammals. In winter flounder, morphine at high doses of 40 mg/kg IP or 17 mg/kg IV produced marked cardiovascular depression that lasted for 48 hours (Newby et al., 2007). Morphine produced antinociceptive effects in rainbow trout using an electrical stimulus, which was blocked by naloxone (Jones et al., 2012). A dose–response relationship was document with a reported ED_{50} of 6.7 mg/kg IP and effects plateaued at approximately 30 mg/kg.

Harms et al. examined the effects of butorphanol and ketoprofen in postoperative Koi. Butorphanol, 0.4 mg/kg IM, produced a significant difference in postoperative behavior in Koi carp as compared to ketoprofen and saline, which may be indicative of an analgesic response (Harms et al., 2005). Butorphanol (10 mg/kg IM) and morphine (5 mg/kg IM) appeared to produce analgesia in postoperative Koi undergoing gonadectomy and morphine was associated with fewer deleterious effects (Baker et al., 2013).

Sedatives and Tranquilizers

Lysa P. Posner

Introduction

Sedatives and tranquilizers are commonly used in veterinary medicine to produce calmness, for chemical restraint, and as an adjunct with general anesthesia. Drugs that produce sedation often have different mechanisms of actions, pharmacodynamic effects, analgesic properties, reversibility, and physiological effects. It is therefore important to understand the different classes of sedative available to be able to predict wanted effects and potential side effects.

Phenothiazine Derivatives

Introduction

Phenothiazines were originally developed and used as antipsychotic drugs for the treatment of schizophrenia in people. However, they have been used in veterinary medicine as tranquilizers since the 1950s. The term *neuroleptic* (antipsychotic) was first used to describe the effects of phenothiazines on the central nervous system, but the more common term, *major tranquilizer*, is still used. The most commonly used phenothiazine in veterinary medicine is acepromazine (ACP). It is incorrectly referred to as "acetylpromazine" in some publications. It is unique because it is not used in human medicine, but has been widely used in veterinary medicine for decades.

Chemistry

Classification: Phenothiazine derivative, major tranquilizer, and antiemetic.

Mechanism of Action

Phenothiazine drugs produce sedation by inhibiting postsynaptic central dopaminergic receptors (D2). Dopamine receptors are included in the family of G-protein-coupled receptors and act as a first messenger by interacting with the receptor proteins of the postsynaptic membrane. This interaction results in transduction of the signal by a guanine nucleotide-binding regulatory protein (G protein) to an appropriate intracellular effector system, or second messenger. Therefore antagonism of the D_2 receptor decreases neurotransmission resulting on behavioral changes (calming and sedation).

Phenothiazines also have antiemetic effects, which are from D2 antagonism at the chemoreceptor trigger zone (Peroutka and Snyder, 1982). Peripherally, and as a side effect, the phenothiazines block the binding of norepinephrine at α-adrenergic receptors (α_1 antagonism). Blockade of these receptors results in peripheral vasodilation.

Indications

Phenothiazines are commonly administered for routine sedation in a variety of species. They are also used in the perianesthetic period to reduce anxiety, reduce induction and maintenance drugs doses, decrease vomiting in susceptible animals, improve the quality of induction and recovery, and to contribute to more balanced anesthesia. Phenothiazines are commonly administered with opioids (e.g., morphine) to produce *neurolept analgesia*; the combination produces synergic effects of each class (i.e., greater sedation and greater analgesia). Phenothiazines can also prevent nausea and vomiting, particularly the vomiting associated with opioid administration (Valverde et al., 2004).

Physiological Effects

Central nervous system effects: All phenothiazines produce a sedation by depressing dopaminergic neurotransmission but vary in potency and duration of action. Phenothiazines decrease spontaneous motor activity in animals, but should not affect coordination. Although sedation is generally reliable, arousal is easily accomplished, particularly in excited or aggressive animals. Extrapyramidal symptoms (rigidity, tremor, akinesia)

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

can be an adverse effect of phenothiazines, particularly at high doses.

Phenothiazines as a class (including acepromazine) have been considered contraindicated for patients with seizure histories, due to a series of experiments in rabbits that showed alteration of the seizure threshold with a proconvulsant drug in patients administered chlorpromazine (Fabisch, 1957). However, there is little scientific evidence that acepromazine induces spontaneous seizures in veterinary patients and recent studies have disputed this conclusion and have even suggested that acepromazine may be anticonvulsant (Tobias et al., 2006; McConnell et al., 2007).

Cardiovascular effects: In addition to blockade of the central effect of dopamine, phenothiazines block peripheral α_1-adrenergic receptors in the vasculature, which results in peripheral vasodilation, and can produces systemic hypotension and a decrease in cardiac output (Stepien et al., 1995). Healthy animals show mild changes to arterial blood pressure; however, the hypotensive effects may be exaggerated in patients that are anesthetized, debilitated, or hypovolemic. A mild reflex tachycardia may be seen in response to hypotension (Turner et al., 1974). Vasoconstrictors, such as phenylephrine, can be used to attenuate the hypotensive effects of phenothiazines (Ludders et al., 1983). The vasodilatory effects generally last longer than the sedation.

Phenothiazines should be used cautiously with locoregional (epidural and intrathecal) anesthetic procedures because they might potentiate the arterial hypotensive effects of local anesthetics. Acepromazine decreases ventricular arrhythmias by raising the arrhythmogenic dose of epinephrine (Muir et al., 1975), even at low doses (Dyson and Pettifer, 1997).

Respiratory effects: Clinical doses of phenothiazines ordinarily have mild effects upon respiratory activity. Respiratory rate is often depressed, but minute volume remains normal (i.e., no change in CO_2). However, respiratory depression may be seen or exaggerated when phenothiazines are administered with other CNS or respiratory depressants (e.g., opioids, isoflurane) or when used at high doses.

Acepromazine attenuates the shunt of ventilation perfusion mismatches seen horses sedated or anesthetized with α_2-agonists and or dissociative anesthetics (Marntell et al., 2005) (see Section Species Differences, Horse).

Musculoskeletal effects: Phenothiazines provide good muscle relaxation and are often used in conjunction with anesthetics that do not provide muscle relaxation or that result in muscle rigidity (e.g., ketamine). The phenothiazine, acepromazine, has been shown to decrease the incidence of malignant hyperthermia in pigs (see Section Species Differences).

Pharmacokinetics and Metabolism

Phenothiazines in general have a large volume of distribution (Vd) and are highly protein bound. In the horse, acepromazine Vd = 6.6 l/kg and is >99% protein bound (Ballard et al., 1982). Time to clinical effect is generally ~10–15 minutes after IV administration and ~30 minutes after IM administration. Acepromazine is long acting in most species; elimination half-life is 3.1 hours in the horse and 7.1 hours in the dog (Ballard et al., 1982; Hashem et al., 1992). Acepromazine undergoes extensive hepatic metabolism and metabolites are excreted in the urine (Dewey et al., 1981). The metabolites of acepromazine have not been evaluated extensively in most species, but horses and humans have differing metabolites and in differing concentrations (Dewey et al., 1981; Elliott and Hale, 1999). Bioavailability in dogs after oral administration is ~20% (Hashem et al., 1992), which must be accounted for if tablets are administered instead of injection. There is no available antagonist to reverse the effects of phenothiazines.

Miscellaneous

Equine recovery from anesthesia: Acepromazine use is associated with decreased perianesthetic morbidity and mortality in horses (Johnston et al., 2002).

Thermoregulation: Patients administered phenothiazines cannot thermoregulate appropriately. Phenothiazines alter thermoregulation by decreased catecholamine binding in the hypothalamus (where thermoregulation is controlled centrally) as well as by altering vasomotor tone in the peripheral vessels that participate in heat retention and elimination. Following administration, patients should be protected from extreme temperature fluctuations (e.g., housed in the sun or in the cold).

Platelet aggregation: The use of acepromazine in patients with coagulopathies is controversial. Acepromazine has been shown to decrease platelet aggregation, which alters coagulation times (Barr et al., 1992). Conversely, administration of acepromazine did not change platelet function via thromboelastography (Conner et al., 2012). Clinically, acepromazine has rarely been implicated in abnormal bleeding. Recommendations for acepromazine use are clinician dependant, although careful consideration in patients with abnormal number or function of platelet, or overt coagulopathy would be prudent.

Hematocrit: Phenothiazines markedly reduce the hematocrit of animals (Parry and Anderson, 1983; Robertson et al., 2001; Ballard et al., 1982). The decrease in packed-cell volume (PCV) by phenothiazines is likely due to splenic sequestration of red blood cells as well as translocation of fluids in response to hypotension. Blood samples drawn from phenothiazine-treated animals for diagnostic purposes should be interpreted accordingly.

Antiemetic: Phenothiazines are antiemetic and have been shown to decrease vomiting in patients when administered with drugs that cause vomiting (e.g., opioids) (Valverde et al., 2004). The antiemetic effects are presumably from the blockade of dopamine receptors in the chemoreceptor trigger zone within the medulla (Peroutka and Snyder, 1982).

Phototoxicity: Phenothiazine derivatives can produce phototoxicity (Elisei et al., 2002), which has been induced in laboratory animals following administration of chlorpromazine in the presence of black-light irradiation (Akin et al., 1979). Although phototoxic reactions in animals do not appear to be an important clinical problem, those with scant hair and white hair probably should not receive excessive exposure to sunlight during treatment with phenothiazines.

Antihistamine: Phenothiazine drugs have antihistaminic (H1) properties (Lichtenstein and Gillespie, 1975). These effects are clinically relevant and these drugs should not be used for skin testing where histamine-caused wheal formation is assessed (Moriello and Eicker, 1991). Although potentially useful for preventing histamine release, the hypotension associated with phenothiazine drugs would preclude their use to treat abnormal histamine release (e.g., mast cell degranulation).

Analgesia: Phenothiazine derivatives provide little or no analgesic activity (Barnhart et al., 2000). Tranquilization with these drugs must be supplemented with analgesics and/or general anesthetics to block nociceptive responses during painful procedures.

Specific Drugs

Many phenothiazines are used to treat psychiatric problems in people and animals. The following three phenothiazines are currently used in veterinary medicine to produce sedation or as an adjunct to anesthesia.

Acepromazine Maleate

Acepromazine is the most commonly used phenothiazine in veterinary medicine. It is routinely used for sedation of many veterinary species, although it only approved for use in dogs, cats, and horses. It is approved for administration IV, IM, or SQ.

Synonym: Acetylpromazine, Vetranquil, ACE, ACP.

Systematic chemical name: 1-[10-[3-(dimethylamino)propyl]-10H-phenothiazin-2-yl ethanone.

Molecular formula: C19-H22-N2-O-S (Figure 14.1).

Molecular weight: 442.5334.

How supplied: Acepromazine is available in yellow aqueous solution at 10 mg/ml and in 5, 10, and 25-mg tablets. The solution should be protected from light.

Dosage for acepromazine: see Box 14.1.

Box 14.1 Dose for acepromazine

Species	Dose and route
Dog and cat	Parenteral sedation: 0.01–0.05 mg/kg IV, IM or SQ Oral sedation: 0.5–2.0 mg/kg PO q 6–8 hours
Horse	Parenteral sedation: 0.01–0.05 mg/kg IV, IM or SQ
Pigs	Parenteral sedation: 0.03–0.2 mg/kg IV, IM, SQ
Cattle	Parenteral sedation: 0.01–0.1 mg/kg IV, IM, SQ
Sheep and goats	Parenteral sedation: 0.05–0.1 mg/kg IV, IM, SQ
Rabbits	Parenteral sedation: 1.0 mg/kg IM, SQ

Promazine Hydrochloride

Promazine is phenothiazine similar to acepromazine. It is rarely used in the parenteral form, but is more popular as a granular oral medication that is mixed with feed for use in horses.

Synonym: Promazine granules, promazine.

Name: 10-(3-dimethylaminopropyl)phenothiazine (Figure 14.1)

Molecular formula: C17-H20-N2-S.Cl-H.

Molecular weight: 442.5334.

How supplied: Promazine granules, 27.5 mg/gram for mixing with feed

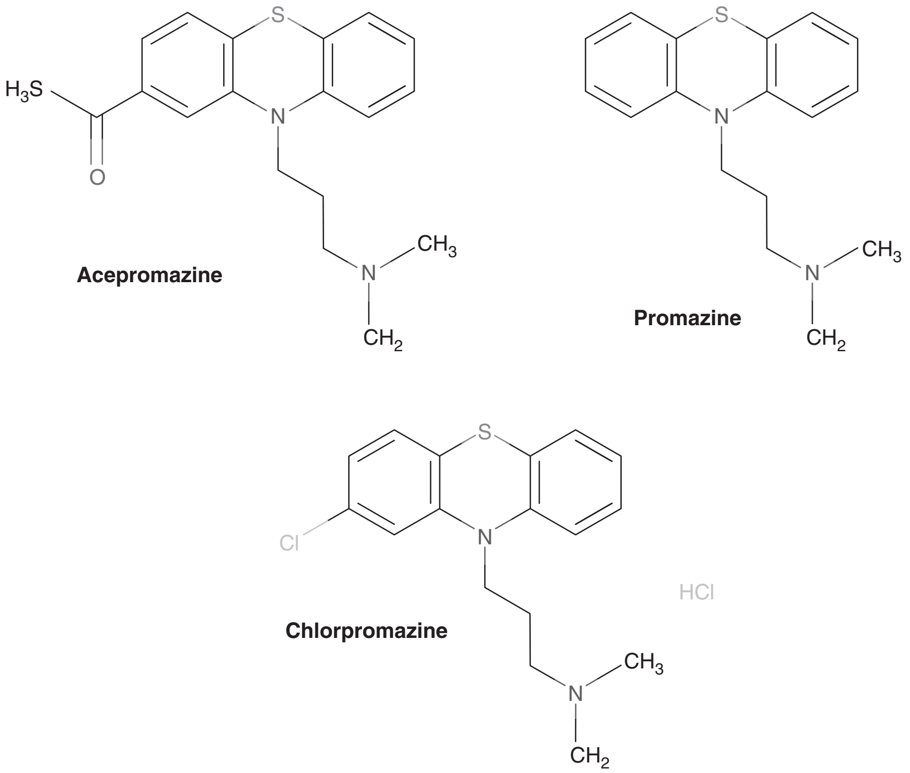

Figure 14.1 Structure of phenothiazines.

Dosage for promazine granules: For horses, mix 1–2 mg/kg of granules with feed. For cattle, mix 1.5–2.75 mg/kg with feed.

Chlorpromazine Hydrochloride

Chlorpromazine is primarily used as an antiemetic in dogs and cats, and less commonly used as a preanesthetic sedative. It is generally contraindicated for use with horses, due to a high incidence of ataxia and altered mentation.

Chemical name: 10-(3-Dimethylaminopropyl)-2-chlorophenothiazine monohydrochloride.

Molecular formula: C17-H19-Cl-N2-S.Cl-H (Figure 14.1).

For the dog and cat, administer 0.55–2.0 mg/kg IV, IM to produce sedation.

Species Differences

Horse: The use of acepromazine in the perianesthetic period is associated with decreased risk of anesthetic morbidity and mortality in horses (Johnston et al., 2002). Acepromazine have been associated with prolonged paraphimosis (penile prolapse) in the horse. Routine sedative doses are generally associated with paraphimosis, which generally resolves within 30 minutes (Ballard et al., 1982). However, in some horses prolapse can remain for greater than 100 minutes, causing swelling (likely in association with vasodilation), trauma, and failure for the penis to retract normally, which creates a management issue and potential for loss of breeding function. In the USA, acepromazine is used with caution in breeding horses, but that concern may be overrated (Driessen et al., 2011). In many parts of the world (e.g., United Kingdom), acepromazine is routinely used for equine anesthesia and has even been associated with better anesthetic outcomes in horses (Johnston et al., 2002). Anecdotal reports suggest pathological paraphimosis does not occur when the total dose does not exceed 10 mg/horse, which was supported retrospectively (Driessen et al., 2011).

Acepromazine attenuates the shunt of ventilation–perfusion mismatches seen horses sedated or anesthetized with α_2-agonists and/or dissociative anesthetics (Marntell et al., 2005). The pulmonary effects are likely due to the combination of improving cardiac output and permitting normal hypoxic pulmonary vasoconstriction (Marntell et al., 2005). Acepromazine produces α_1-adrenergic blockade, which balances the vasoconstriction of α_2-agonist sedative drugs. Vasoconstriction and the reflex bradycardia associated with α_2-agonists are major causes of decreased cardiac output. Additionally, the rise in pulmonary arterial pressure (PAP) associated with α_2-agonists and dissociative anesthetics likely interfere with hypoxic pulmonary vasoconstriction. Hypoxic pulmonary vasoconstriction is the normal mechanism to limit ventilation and perfusion mismatches.

Chlorpromazine is not recommended in horses due to extreme ataxia and altered mentation.

Dog: Some Boxer dogs have an exaggerated response to the phenothiazine, acepromazine (Brock, 1994). In those dogs, sedation and hypotension are greater than expected and there have been anecdotal reports of syncopal episodes, presumably from hypotension. Aggressive symptomatic treatment of hypotension has resulted in full recoveries. Therefore acepromazine might be avoided all together in Boxer dogs or used at much reduced doses with monitoring for any untoward effects.

Dogs with high vagal tone (Bulldogs, Boxers) have anecdotally been reported to have greater morbidity and mortality when administered acepromazine, presumably caused by the adrenergic blocking effects of the drug. Similar recommendations for avoidance or reduced dosages have been made.

Pig: Acepromazine may prevent the occurrence of halothane-induced malignant hyperthermia in susceptible pigs (McGrath et al., 1981).

Drug Interactions

All phenothiazines should be used cautiously with any drugs that also produce vasodilation or hypotension. All phenothiazines when administered with other CNS depressants can produce exaggerated CNS depression. Doses of one or both drugs might need to be reduced.

Overdose/Acute Toxicity

The phenothiazines have very high therapeutic indexes, particularly when used in conscious (nonanesthetized) animals. (Stoelting, 1999). Dogs that received more than 100 times the recommended oral dose had no fatalities. This safety margin is likely diminished in anesthetized patients where many protective reflexes are attenuated.

Contraindications

Phenothiazines should be avoided in patients that are dehydrated, hypovolemic, bleeding, or in shock because of the drugs effect on vessel tone (vasodilation). Phenothiazines should be used cautiously in patients with coagulopathies or thrombocytopenia due to their effect on platelet aggregation (see Section Miscellaneous). Phenothiazines should be used cautiously in Boxer dogs, brachiocephalic dogs, breeding stallions, or debilitated animals.

Regulatory Information

Controlled drug status: Acepromazine is a nonscheduled drug.

Withdrawal times: No listed withdrawal times for the dog, cat, or horse; however, phenothiazines should not to be used in horses intended for human consumption.

Veterinary Approved Products (Representative)

Acepromazine

Acepromazine is approved by the FDA for use in dogs, cats and horses.

Acepromazine Maleate Injection 10 mg/ml (Boehringer Ingelheim Vetmedica, Inc.).
Acepromazine Maleate 10 or 25-mg Tablets (Boehringer Ingelheim Vetmedica, Inc.).

Promazine

Promazine is approved by the FDA for use in dogs, cats, and horses.

Promazine HCl Injectable 50 mg/ml (Zoetis)
Promazine HCl Granules 10.25 oz containers, 27.5 mg/gram (Zoetis).

Chlorpromazine

There are no veterinary approved products. It is supplied as 25 mg/ml injection for human use (Thorazine, and generic brands), and is used off label in veterinary patients. It is also supplied in 10, 25, 50, 100, and 200-mg tablets for people.

Butyrophenone Derivatives

Introduction

Butyrophenone drugs (haloperidol and droperidol) were first introduced into human medicine in the late 1950s as antipsychotics. Haloperidol is still used as an antipsychotic and droperidol is primarily used to prevent postoperative nausea and vomiting. Droperidol was used in veterinary medicine primarily as a sedative, but is no longer marketed due to adverse behavioral effects. There was previously a formulation called “Innovar-Vet”, which was a combination of droperidol and fentanyl citrate for injection, but this product is no longer marketed. More information regarding droperidol may be found in previous editions of this text. Butyrophenones are less commonly used in veterinary medicine; however, azaperone is still used for sedation in veterinary medicine in swine and zoo/wildlife medicine.

Chemistry

Classification: Butyrophenones are neuroleptic sedatives, and still one of the major classes of antipsychotic drugs in use in human medicine.

Mechanism of Action

The CNS effects of butyrophenones are primarily due to the antagonism of D_2 receptors in mesolimbic–mesocortical pathways in the brain, but there is also antagonism at D_1, 5-HT, α_1, and histamine receptors (Potter and Hollister, 2001). Some of the adverse signs associated with butyrophenones, such as extrapyramidal signs, tardive dyskinesis, muscle tremors, and restlessness, are associated with dopaminergic antagonism of the nigrostriatal pathways (Potter and Hollister, 2001). Although butyrophenones produce α_1-adrenergic receptor antagonism (vasodilation), there is less affinity for these receptors, which explains why butyrophenones do not cause the same degree of hypotension as compared to the phenothiazines (Stoelting, 1999).

Indications

Azaperone is used mainly in swine for its calming effects when mixing weanlings and feeder pigs, to prevent maternal aggression, for transportation, and for obstetrical conditions. Azaperone has also been used as an anesthetic adjunct and sedative in a number wildlife species (Morkel et al., 2010; Radcliffe et al., 2000; Williams et al., 1981; Still et al., 1996).

Azaperone

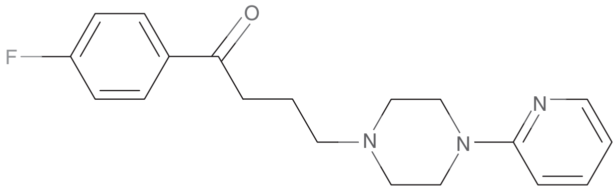
Synonym: Stresnil, Suicalm, Fluoperidol, Eucalmyl, Sedaperone.

Systematic chemical name: 1-(4-fluorophenyl)-4-(4-pyridin-2-ylpiperazin-1-yl)butan-1-one (Figure 14.2).

Molecular weight: 327.4 g/mol.

Molecular formula: C19-H22-F-N3-O.

The water solubility is 131 mg/l.



Azaperone

Figure 14.2 Structure of azaperone.

Pharmacodynamic Effects

Central nervous system effects: Azaperone produces varying levels of sedation depending on species and dose. Its effects range from behavior modification to chemical restraint (Radcliffe et al., 2000; Nishimura et al., 1993; Clutton et al., 1997; Serrano and Lees, 1976). However, there have been isolated reports of paradoxical excitement following intravenous administration of azaperone in the horse (Dodman and Waterman, 1979).

Cardiovascular effects: Azaperone causes a decrease in blood pressure, presumably from reduction in systemic vascular resistance from α_1-adrenergic blockage (Clarke, 1969). The hypotension may be associated with an increase in heart rate. It is unclear if the increase in heart rate is a response to hypotension or from a central vagolytic effect (Nashan et al., 1984; Serrano and Lees, 1976), or both. The cardiovascular changes lasted longer than the sedative effects of azaperone.

Respiratory effects: Azaperone generally produces mild respiratory depression. Respiratory depression may be enhanced when combined with other CNS depressants. Interestingly, there have been reports of increase in respiratory rates in rats, horses, and pigs (Fish et al., 2011).

Musculoskeletal effects: Azaperone produces muscle relaxation similar to the phenothiazine, acepromazine.

Miscellaneous: Packed cell volume (PCV) decreases following administration. The fall in PCV is presumably secondary to vasodilation, which would result in splenic sequestration of erythrocytes and translocation of fluid into the intravascular space in response to hypotension.

Analgesia: Butyrophenones do not interrupt the pain pathway and azaperone did not produce any analgesia in a mechanical nociceptive stimulus model in laboratory animals (Mataqueiro et al., 2004).

Pharmacokinetics Properties

There is limited information regarding the pharmacokinetics of the butyrophenones in veterinary species. The onset time after intramuscular injection is less than 10 minutes in most species with a peak effect seen approximately 30 minutes after administration (Serrano and Lees, 1976). The duration of action is 2–4 hours in pigs, longer in older pigs. Azaperone in pigs is biotransformed in the liver with 13% excreted in the feces. In rats, 25% of the drug in removed via the kidney and 10% is excreted unchanged (Fish et al., 2011). Metabolite residues are highest in the kidneys and are present in the urine for at least 3 days after administration;

however, most of the drug is eliminated from the body with 16 hours (Arneth, 1985).

Adverse Effects/ Contraindications

Thermoregulation: The ability to thermoregulate is decreased in patients administered butyrophenones. The effect on thermoregulation is a combination of α_1-receptors blockage (vasodilation) as well as antidopaminergic effects in the thermoregulatory centers in the medulla. Care should be taken when these drugs are administered to patients in cold temperatures as their normal compensatory response of vasoconstricting vessels to conserve heat loss is compromised.

Dysphoria and akathisia: Butyrophenones may produce dysphoric effects, especially in patients with a high level of anxiety. Humans describe a feeling of restlessness (akathisia), which may manifest as pacing and agitation in veterinary patients. Extrapyramidal signs are seen in 1% of human patients with the use of droperidol. These droperidol-induced extrapyramidal signs may be treated with diphenhydramine IV (Stoelting, 1999). Muscle tremors, spasticity, and irritability have been seen in the dog after the use of high doses in the range of 11–22 mg/kg IV. Salivation, sweating, muscle tremors, and vocalization has been reported in the horse following intravenous administration of azaperone at a dose of 0.29–0.57 mg/kg (Dodman and Waterman, 1979).

Paraphimosis: Doses of azaperone greater than 1 mg/kg IM may cause penile prolapse in boars, which may predispose to injury. Paraphimosis is presumably secondary to vasodilatory effects.

Representative Veterinary Dosages

See Box 14.2.

Box 14.2 Doses for azaperone

Species	Dose and route	Reference
Swine	0.4 – 2.2 mg/kg IM	
Horse	0.4 – 0.8 mg/kg IM (Intravenous administration is not recommended due to the paradoxical excitement seen in a high percentage of horses)	(Dodman and Waterman, 1979)
Deer	0.3 mg/kg IM in combination with xylazine 1 mg/kg IM	(Read and McCorkell, 2002)
Rhinoceros	0.04 mg/kg IM	(Radcliffe et al., 2000)
Elephant	50–120 mg per elephant IM	(Stegmann, 1999)

How supplied: Azaperone comes as a clear, pale yellow sterile injectable solution with a concentration of 40 mg/ml in a 100 ml multidose bottle. Azaperone should be discarded 28 days after the multidose vial has been opened.

Drug Interactions

Butyrophenones potentiates the effects of other anesthetic agents (CNS depressants), which will necessitate a reduction in the dose of induction and inhalational agents (Geel, 1991; Bustamante and Valverde, 1999; Nunes et al., 2001; Yamashita et al., 2003). Butyrophenones inhibit the effect of dopamine on renal blood flow (Bradshaw et al., 1980). The use of butyrophenones in patients receiving selegiline may precipitate extrapyramidal movement signs.

Overdose/Acute Toxicity

There are no known antagonists for butyrophenone drugs and treatment for overdoses should focus on supportive care. Patients should be monitored for hypotension and respiratory depression and treated accordingly.

Regulatory Information

Controlled drug status: Azaperone in a nonscheduled drug.

Withdrawal times: FARAD has no withdrawal times listed for azaperone in pigs. However, a 10-day withholding period prior to slaughter has been recommended.

Veterinary Approved Products (Representative)

Azaperone: Stresnil, Azaperone 40 mg/ml (Elanco, Eli Lilly).

Benzodiazepine Derivatives

General Pharmacological Considerations

History/ Introduction

The first benzodiazepine, chlordiazepoxide, was discovered accidently in 1954 by Dr Leo Sternbach. Diazepam (Valium$^{®}$) is a simplified version of chlordiazepoxide and was marketed in 1963 for anxiety. Although many benzodiazepines (>50) are used in people and animals for behavioral modification, only diazepam, midazolam, lorazepam, and zolazepam will be discussed as sedatives and adjuncts to veterinary anesthesia. The use of benzodiazepines for managing behavior problems in animals is discussed in Chapter 18.

Classification

Benzodiazepines are sedative-hypnotics due of their propensity to cause anxiolysis, sedation, and an ability to cause sleep. They are classified as minor tranquilizers.

Chemistry: A benzodiazepine consists of a benzene ring which is fused to a seven-member diazepine ring (Figure 14.2). All of the clinically useful benzodiazepines and most of the active metabolites contain an aryl substitute at the 5th position of the diazepine ring as well as N-substitutions at the 1st and 4th positions (5-aryl-1,4-benzodiazepine). The hypnotic-sedative action of these drugs is due to the substitution of a halogen or a nitro group at the 7th position of the benzodiazepine structure.

Mechanism of Action

Benzodiazepines bind to the benzodiazepine receptor binding site on the gamma subunit of the gamma-aminobutyric acid receptor subtype A ($GABA_A$). Gamma-aminobutyric acid (GABA) is the primary inhibitor neurotransmitter in the CNS. Activation of the benzodiazepine receptor enhances the effects of GABA on the $GABA_A$ receptor. $GABA_A$ is a large macromolecule, which also contains a number of binding sites for other sedative drug classes such as barbiturates and alcohols. This explains the synergistic effect of these drugs on $GABA_A$-mediated inhibition of the CNS. Activation of the benzodiazepine binding site on $GABA_A$ receptors increase the frequency of the opening of the chloride ion channel, leading to hyperpolarization of the postsynaptic neuron (Yeh et al., 1988), producing decreased neuronal transmission. The heterogeneity of the $GABA_A$ subunits is in part responsible for the differing clinical actions of the various benzodiazepines (Upton et al., 2001). The highest concentration of $GABA_A$ receptors is found in the cerebral cortex, with very few receptor sites found outside the CNS, hence the minimal cardiopulmonary effects of benzodiazepine drugs (Cornick-Seahorn and Seahorn, 1998).

Indications

Benzodiazepines are used in veterinary medicine as: anticonvulsants (Chapter 17); adjuncts to anesthetic induction agents; skeletal muscle relaxants; and for behavioral modification (anxiolysis and sedation) (Chapter 18). In the healthy patient, behavioral effects are mild, and may be paradoxical as the reduction in inhibitions can result in vocalization, excitement, and dysphoria. Sedation is more reliable in neonates, geriatrics, or ill patients, or as the author would say “very young, very old, or very sick.” In small ruminants benzodiazepines are generally effective at causing sternal recumbency and sedation.

Pharmacodynamic effects

Central nervous system effects: A common use for benzodiazepines is to produce sedation; however, when used alone they can cause unpredictable results. This is especially true in healthy individuals. Paradoxical excitement, agitation, vocalization, and dysphoria may be seen after IV or IM administration. Benzodiazepines are commonly combined with other agents such as opioids, α_2-adrenergic agonists (see Section Alpha-2-Adrenergic Receptor Agonists), or NMDA receptor antagonists (e.g., ketamine) to provide a more predictable sedation or chemical restraint. Benzodiazepines can by anxiolytic (hence their use in people to treat phobias), but the decrease in inhibitions can result in unpredictable behavior in veterinary patients. The CNS depression produced by benzodiazepines can reduce the requirements for anesthetic induction agents and lower the inhalant needs. Diazepam potentiates the opioid reduction in the MAC of inhalant anesthesia (Hellyer et al., 2001; Seddighi et al., 2011).

Benzodiazepines have a favorable profile with regard to cerebral perfusion, which and makes them useful drugs in the face of central CNS disease. They cause a reduction in cerebral blood flow and an even greater reduction in oxygen consumption (Reves et al., 1985; Hoffman et al., 1986). Diazepam caused a reduction in theta, delta, alpha, and beta-frequencies of the electroencephalogram of anesthetized dogs without any changes to the cardiovascular parameters (Court and Greenblatt, 1992). Diazepam, like other benzodiazepines is anticonvulsant (Wauquier et al., 1979; Podell, 1995, 1996). Anticonvulsants are discussed further in Chapter 17.

Cardiovascular effects: Clinical doses of benzodiazepines cause minimal cardiovascular depression (Jones et al., 1979) and are commonly administered to patients with cardiovascular disease (Harvey and Ettinger, 2007). At clinical doses, both midazolam and diazepam have minimal effect on cardiac output, stroke volume, systemic vascular resistance, or coronary blood flow (Jones et al., 1979).

Respiratory effects: At clinical doses, benzodiazepines may decrease respiratory rate, but rarely affect ventilation and oxygenation (McDonell and Kerr, 2007). However, at higher doses, there can be a dose-dependent respiratory depression and any respiratory depression may be exaggerated when benzodiazepines are combined with other CNS depressants or when administered to debilitated patients (McDonell and Kerr, 2007).

Musculoskeletal effects: Benzodiazepines potentiate the GABA-ergic mediated muscle relaxation of inhibitory neurons at the level of the spinal cord (Elliott,

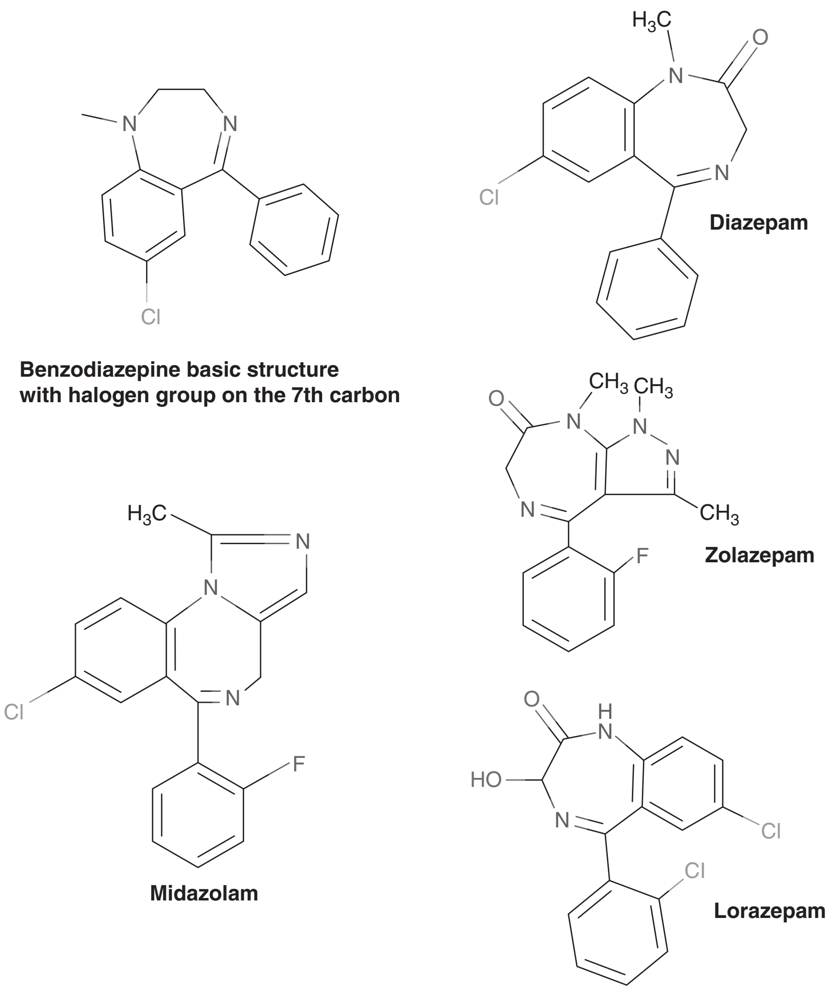


Figure 14.3 Benzodiazepines.

1976), which produces reliable muscle relaxation. Benzodiazepines are often administered with other anesthetic drugs that do not provide sufficient muscle relaxation alone (e.g., ketamine, etomidate; see Chapter 12). At the clinical doses, midazolam can cause ataxia and in some species is capable of causing recumbency (Platt et al., 2000). The effects of benzodiazepines with nondepolarizing neuromuscular antagonists are unclear. In an in vitro study using cat muscle, midazolam and diazepam were shown to potentiate neuromuscular blockade (Driessen et al., 1987a); however, in humans, midazolam was not shown to change the blockade or rocuronium (Hepağuşlar et al., 2002).

Analgesia: Benzodiazepines do not affect the pain pathway and therefore do not produce analgesia.

Specific Drugs

Diazepam Hydrochloride

Synonyms: Valium, Apozepam.

Molecular formula: C16-H13-Cl-N2-O (Figure 14.3).

Molecular weight: 284.7447.

Chemical name: 2H-1,4-Benzodiazepin-2-one, 7-chloro-1,3-dihydro-1-methyl-5-phenyl.

Diazepam has been used clinically since 1963 and is often the standard against which all other benzodiazepines are measured. Diazepam is a highly lipid-soluble benzodiazepine which has a much shorter duration of action in the dog and cats compared with horses or people (Table 14.1).

Many of the unwanted side effects of diazepam are caused by the hyperosmotic vehicle, propylene glycol (see below in this section) and therefore large volumes or constant rate infusions should be administered with caution. It may not be compatible with some aqueous IV fluids. Additionally, propylene glycol can result in erratic absorption with any route other than IV (Divoll et al., 1983).

Diazepam can administered rectally and is available in suppository form as an anticonvulsant for children

Table 14.1 Benzodiazepine pharmacokinetics in various species

Drug	Species	Dose (mg)	Volume of distribution (l/kg)	Protein binding (%)	Clearance (ml/kg/min)	Elimination half-life (minutes)	Reference
Diazepam	Dog	0.5 mg/kg IV				14–16	(Papich and Alcorn, 1995)
	Dog	2.0 mg/kg IV				192	(Löscher and Frey, 1981)
	Cat	5.0 mg/kg IV			4.72 ± 2.45	330	(Cotler et al., 1984)
	Horses	0.2 mg/kg IV				210–1320	(Muir et al., 1982)
Midazolam	Dog	0.5 mg/kg IV	3.0 ± 0.9	96		59–95	(Court and Greenblatt, 1992)
	Dog	0.2 mg/kg IV	1.1 ± 0.68		10.1 ± 1.9	63.3 ± 28.5	(Schwartz et al., 2013)
	Horse	0.1 mg/kg IV	2.8 (2.2–7.0)		10.4 (8.4–17.6)	408 (192–924)	(Hubbell et al., 2013)
Lorazepam	Dog	0.3 mg/kg IV	100 ± 15 l				(Podell et al., 1998)

(Knudsen, 1979). In dogs, diazepam at 2 mg/kg via rectal suppository did not result in clinically useful plasma levels of diazepam (Probst et al., 2013); however, the active benzodiazepine metabolites were produced in dogs administered the same dose, which indicates good rectal absorption (Papich and Alcorn, 1995).

Hemolysis: Propylene glycol, the vehicle of diazepam, can cause lysis of red blood cells (RBC), particularly in cats (Christopher et al., 1989). Large volumes or constant rate infusion may cause clinical hemolysis and therefore should be administered with discretion.

Pain on administration: Diazepam may cause pain when administered intravenously or intramuscularly (Olesen and Hüttel, 1980). The pain is associated with the vehicle, propylene glycol. Propylene glycol vehicles have also been associated with increased risk of thrombophlebitis (Doenicke et al., 1994). Clinical ways to decrease the pain for the patient involve administration in a larger vein or through a running fluid line to provide dilution.

Hepatic necrosis in cats: Repeated oral administration of diazepam has been associated severe life-threatening hepatic necrosis in cats (Center et al., 1996). No definitive cause has been established, but it is not recommended to use the oral preparation of diazepam in cats (Center et al., 1996).

Appetite stimulation: Diazepam administered intravenously is an appetite stimulant, particularly in cats (Mereu et al., 1976) and goats (Miert et al., 1989). The mechanism of action is unknown, but may be associated with decreased inhibitions or serotonergic mechanisms. Anorexia due to GI stasis should not be treated with diazepam since diazepam also slows down gastric emptying (Steyn et al., 1997).

Pharmacokinetic Data

See Table 14.1.

Representative Veterinary Dosage

See Box 14.3.

Box 14.3 Diazepam dosages

Species	Dose and route
Dog and cat	Sedation: 0.1–0.5 mg/kg IV. (IM administration is no longer recommended since propylene glycol is painful on IM injection and absorption is erratic (compared with IV dosing). Rectal dose: 0.2–2.0 mg/kg Adjunct induction agent: 0.1–0.2 mg/kg IV[a] Anticonvulsant: 0.5–1.0 mg/kg IV Appetite stimulant in cats: 0.05 mg/kg IV
Horses	Neonatal sedation: 0.05–0.2 mg/kg IV Adjunct to anesthesia induction: 0.05–0.1 mg/kg IV Anticonvulsant: 0.02–0.4 mg/kg IV
Small ruminants	Sedation: 0.1–1.0 mg/kg IV Adjunct to anesthesia induction: 0.05–0.3 mg/kg IV Appetite stimulation (goats): 0.06 mg/kg IV

[a] Diazepam is often used as an induction synergistic adjunct to propofol, ketamine, or etomidate at a rate of given immediately before the induction agent.

Regulatory Information

Controlled drug status: Diazepam is a DEA Schedule IV drug

Withdrawal times: None of the benzodiazepine drugs are intended for food producing animals and there are no established withdrawal times.

Veterinary Approved Products

There are no FDA veterinary approved products.

How supplied: Injectable formulations of diazepam consist of a 5 mg/ml solution with 40% propylene glycol, 10% ethanol, 5% sodium benzoate/benzoic acid buffer, and 1.5% benzyl alcohol as a preservative. The solution is buffered to a pH of 6.2–6.9. Propylene glycol and ethanol allow the diazepam to be dissolved into solution. The cloudy appearance of solutions does not alter the potency of diazepam; however, do not administer if a precipitate forms and does not clear.

Midazolam Maleate

Synonyms: Versed, Dormicum, Hypnovel, Rocam.

Molecular formula: C18-H13-Cl-F-N3 (Figure 14.3).

Molecular weight: 325.7727.

Chemical name: 4H-Imidazo(1,5-a)(1,4)benzodiazepine, 8-chloro-6-(2-fluorophenyl)-1-methyl-

Midazolam is a water-soluble benzodiazepine. The chemical structure of midazolam produces both water and lipid solubility based on pH (Kanto, 1985). The pH of marketed midazolam is acidic (pH = 3.5). The low pH stabilizes the diazepine ring and increases water solubility. After administration the pH increases to >4.0 (physiological pH), which causes the diazepine ring to open, increasing the lipid solubility (Kanto, 1985). Therefore at injection the drug is more water soluble but quickly becomes more lipid soluble once in the body.

The lack of propylene glycol allows administration IV, IM, and likely SQ, with reliable bioavailability (Schwartz et al., 2013). Midazolam can also be absorbed intranasally (Henry et al., 1998). However, unlike diazepam, midazolam administered rectally does not result in clinically useful plasma concentrations and cannot be recommended (Schwartz et al., 2013).

Midazolam is more potent than diazepam, but has similar pharmacodynamics and is often used interchangeably in the clinical setting. The fact that midazolam can be administered via a variety of routes, it does not cause pain on injection (no propylene glycol), and has a lower cost than diazepam has made midazolam more commonly used in veterinary medicine.

Pharmacokinetic Data

See Table 14.1.

Representative Veterinary Dosages

See Box 14.4.

Box 14.4 Midazolam dosages

Species	Dose and route
Dog and cat	Sedation: 0.1–0.4 mg/kg IV, IM, SQ 0.2–1.0 mg/kg intranasal Adjunct to anesthesia induction agent: 0.1–0.3 mg/kg IV Anticonvulsant: 0.5–1.0 mg/kg IV
Ruminants	Sedation: 0.1–1.0 mg/kg IV Adjunct to anesthesia induction agent: 0.1 mg/kg IV
Horse	Neonatal sedation: 0.05–0.2 mg/kg IV Adjunct to anesthesia induction: 0.05–0.1 mg/kg IV Anticonvulsant: 0.02–0.4 mg/kg IV

How Supplied

The clinical preparations of midazolam are water based (not in propylene glycol) and buffered to a pH of 3.5. Midazolam is compatible with normal saline and lactated Ringer's solution.

Regulatory Information

Controlled drug status: Midazolam is a DEA Schedule IV drug.

Withdrawal times: None of the benzodiazepine drugs are intended for food-producing animals and there are no established withdrawal times.

Veterinary Approved Products

There are no FDA veterinary approved products.

How supplied: Midazolam hydrochloride: Each ml contains midazolam hydrochloride equivalent to 1 mg or 5 mg midazolam compounded with 0.8% sodium chloride. The pH is approximately 3 (2.5 to 3.5) and is adjusted with hydrochloric acid and, if necessary, sodium hydroxide.

Lorazepam

Synonym: Ativan.

Molecular formula: C15-H10-Cl2-N2-O2.

Molecular weight: 321.162.

Chemical name: 10-chloro-2-(2-chlorophenyl)-4-hydroxy-3,6-diazabicyclo[5.4.0]undeca-2,8,10,12-tetraen-5-one (Figure 14.3).

Lorazepam is a benzodiazepine drug that can be administered orally and parenterally. In humans, lorazepam is the drug of choice for status epilepticus due to its higher binding affinity to the benzodiazepine receptor and elevated brain concentrations (Podell et al., 1998). It achieves therapeutic levels when administered IV but does not when administered rectally (Podell et al., 1998). Intramuscular bioavailability is veterinary species is unknown, but it is well absorbed in people (Wermeling et al., 2001). Injectable lorazepam is supplied in propylene glycol, which can result in pain on administration and hemolysis, similar to diazepam (Cawley, 2001). In veterinary medicine it is uncommonly used as a sedative or anticonvulsant, but its oral bioavailability makes it suitable as an anxiolytic (Sherman, 2008).

Representative Veterinary Dosages

Dog for anxiolytic effects: 0.02–0.1 mg/kg PO BID (Sherman, 2008).

Regulatory Information

Controlled drug status: Lorazepam is a DEA Schedule IV drug.

Withdrawal times: None of the benzodiazepine drugs are intended for food-producing animals and there are no established withdrawal times.

Veterinary Approved Products

There are no FDA veterinary approved products

How supplied: The vehicle of lorazepam consists of propylene glycol 79%, polyethylene glycol 18–20%, and benzyl alcohol 2% (v/w %). Each ml contains 2 mg or 4 mg.

Zolazepam

Synonym: zolazepam HCL.

Molecular formula: C15-H15-F-N4-O (Figure 14.3).

Molecular weight: 286.3085.

Chemical name: Pyrazolo(3,4-e)(1,4)diazepin-7(1H)-one, 4-(2-fluorophenyl)-6,8-dihydro-1,3,8-trimethyl-

Zolazepam is also a water-soluble benzodiazepine, but at acid and physiological pH. In the USA, it is only available in combination with tiletamine, an NMDA antagonist (like ketamine), in the anesthetic drug Telazol® (see Chapter 12 for additional information). Little clinical information exists on zolazepam alone.

Representative Veterinary Dosages

Zolazepam is only available as part of the mixture of Telazol (see Chapter 12 for dosing of that product).

Regulatory information

Controlled drug status: Zolazepam is a DEA Schedule III drug. Note, zolazepam is only available as part of the combination drug Telazol, which is a DEA schedule III drug.

Withdrawal times: None of the benzodiazepine drugs are intended for food-producing animals and there are no established withdrawal times.

Veterinary Approved Products

Zolazepam as part of the combination product Telazol® is the only FDA-approved benzodiazepines for us in dogs and cats.

How supplied: Zolazepam is supplied only with tiletamine as a powder that is reconstituted to 5 ml of solution. Each ml contains 50 mg zolazepam (and 50 mg tiletamine). The reconstituted solution has a pH of 2.2–2.8.

Species Differences

Cat: There have been case reports of cats developing hepatic failure following repeated oral administration of diazepam (see Section Diazepam Hydrochloride). Diazepam is an appetite stimulant, particularly in cats (see Section Diazepam Hydrochloride).

Horses: In adult horses, and depending on dose, midazolam may not produce sedation (Hubbell et al., 2013) or can cause pacing, paddling, and agitation (Löscher and Frey, 1984). Benzodiazepines are rarely used alone in adult horses for sedation.

Zolazepam and veterinary species: (See also Chapter 12.) Zolazepam is metabolized at different rates in different species. This is clinically relevant as it is combined with tiletamine in the product Telazol. Therefore recovery (time and smoothness) from Telazol can be very different in different species.

Cerebral uptake of benzodiazepines: There are some species differences in the cerebral uptake of benzodiazepines in various species. In cats and sheep, midazolam is taken up by the cerebrum faster than diazepam; however, the converse is true for pigs (Upton et al., 2001). This is in part due to the lower brain : blood partition coefficient of midazolam when compared with diazepam. In dogs, the free unbound portion of the benzodiazepines correlates well with the concentration of these corresponding compounds to brain tissue levels (Wala et al., 1991).

Metabolism

Benzodiazepines undergo liver metabolism, but the pathways (e.g., reduction, glucuronidation) differ based on the drug and species. Additionally, many of the benzodiazepines have a number of have active metabolites such as desmethyldiazepam, oxazepam, and temazepam (Upton et al., 2001), which also varies by drug and species. Desmethyldiazepam is the main metabolite in most species (Wala et al., 1991), and appears to have the most clinical effect due to its long half-life. Approximately 50% of diazepam is metabolized to desmethyldiazepam in the cat (Cotler et al., 1984). Following glucuronide conjugation benzodiazepines are excreted in the urine (Martin et al., 1990); however, cats perform glucuronidation much slower than other species (Driessen et al., 1987b).

Adverse Effects/ Contraindications

Paradoxical excitation

It is not uncommon to see a transient period of agitation, vocalization, or excitement following parenteral benzodiazepine administration in a number of species. This unwanted effect is seen more commonly in healthy animals, and less commonly in very young, very old, or ill patients. Since, benzodiazepine drugs when used alone can produce unpredictable behavioral effects, they are often administered in conjunction with other CNS depressants to minimize the risk of paradoxical excitation.

Behavioral disinhibition

As an anxiolytic, benzodiazepines can decrease inhibitions. Therefore caution should be used when sedating animals exhibiting fear-induced aggression, as the disinhibition caused by the benzodiazepines may provoke aggressive behavior.

Hepatic Necrosis in Cats with Oral Diazepam

See Section Diazepam Hydrochloride.

Addiction/Physical Dependence

Patients discontinuing a benzodiazepine require their dose to be tapered off to avoid abstinence syndrome from sudden cessation. Long-term use of benzodiazepines does cause physical dependence in the dog (McNicholas et al., 1983) and the use of flumazenil may precipitate abstinence syndrome (tremors, hot foot walking twitches, tonic clonic seizures, and occasional death) (Oliver et al., 2000; Klotz, 1988).

Drug Interactions

The administration of other CNS depressants (e.g., inhalant anesthetics, propofol, opioids, α_2-adrenergic agonists) with a benzodiazepine often results in an additive or synergistic CNS depressant effect (Short and Chui, 1991). Therefore dosing of benzodiazepine or other drugs may need to be adjusted.

Diazepam is absorbed by the polyvinylchloride (PVC) materials commonly used in IV solution lines, bags, and syringes (Kowaluk et al., 1983; Daniell, 1975), with up to 50% of the drug being absorbed (Ball and Tisocki, 1999). This can be clinically relevant for patients receiving constant rate infusions or if storing diazepam in administration sets. This binding does not occur with hard plastic (e.g., syringes) when used for administration.

Benzodiazepines that first undergo oxidation as part of their hepatic metabolism, such as diazepam or midazolam, may have reduced metabolism if coadministered with cimetidine, erythromycin, isoniazid, ketoconazole (KuKanich and Hubin, 2010), propranolol and valproic acid, whereas rifampin will increase the metabolic rate of benzodiazepines (Lam et al., 2003).

Overdose/Acute Toxicity

Clinical signs of acute intoxication can include ataxia/disorientation, CNS depression or agitation, respiratory depression, weakness, tremors, vocalization, tachycardia, tachypnea, or hypothermia. Treatment should include the use of the specific benzodiazepine antagonist, flumazenil (see Section Flumazenil), and supportive care.

Benzodiazepine Antagonists

General Pharmacological Considerations

History/ Introduction

Flumazenil was introduced in 1987 by Hoffmann-La Roche under the trade name Anexate^{TM}. It is the only benzodiazepine antagonist available in the USA. It has also been marketed under the trade name Romazicon, but is currently used as a generic.

Classification

Flumazenil is a specific and exclusive benzodiazepine competitive antagonist with a high affinity for the benzodiazepine receptor site of the $GABA_A$ receptor. Flumazenil has virtually no agonist activity at the benzodiazepine receptor site.

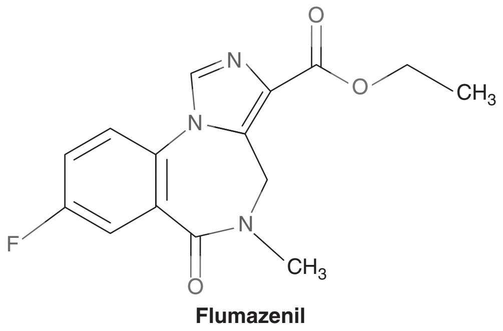

Figure 14.4 Flumazenil.

Specific Drugs

Flumazenil

Molecular formula: C15-H14-F-N3-O3 (Figure 14.4).

Molecular weight: 303.3 g/mol.

Systematic chemical name: 4H-Imidazo(1,5-a)(1,4) benzodiazepine-3-carboxylic acid, 8-fluoro-5,6-dihydro-5-methyl-6-oxo-, ethyl ester.

Mechanism of Action

Flumazenil competitively antagonizes the action of benzodiazepines on the benzodiazepine receptor binding site on the $GABA_A$ receptor. Activation of the $GABA_A$ receptor results in increased chloride conduction and subsequent hyperpolarization of the postsynaptic membrane (decreased neural conduction). Antagonism of this effect results in more active neural conduction. Flumazenil only binds and antagonizes the benzodiazepine binding site of the GABA receptor. Therefore, it does not antagonize the CNS effects of other $GABA_A$ receptor sedative-hypnotics at such as propofol or ethanol. Flumazenil antagonizes endogenous benzodiazepine-like substances, which are elevated in human patients with hepatic encephalopathy (Grimm et al., 1988).

Indications

Flumazenil is indicated for the competitive reversal of benzodiazepine agonists.

Pharmacodynamic Effects

Central nervous system effects: Flumazenil attenuates the CNS depressant effects of benzodiazepine drugs. Flumazenil reverses the electroencephalographic changes induced by benzodiazepine in the dog and horse (Greene et al., 1992; Keegan et al., 1993; Johnson et al., 2003; Artru, 1989). In people, flumazenil in the absence of a benzodiazepine did not cause CNS excitement (Forster et al., 1993).

The benzodiazepine antagonist, sarmazenil, has been shown to be useful in the treatment of hepatic encephalopathy (Grimm et al., 1988); however, flumazenil has been shown minimal effect in reversing the effects of hepatic encephalopathy (Grimm et al., 1988; Meyer et al., 1998).

Cardiovascular effects: Flumazenil has no direct effect on left ventricular function or coronary hemodynamics observed in human patients (Marty et al., 1991); however, in cats flumazenil administered after diazepam or midazolam antagonized the fall in blood pressure caused by the benzodiazepines agonists (Driessen et al., 1987c).

Musculoskeletal effects: Flumazenil is effective in reversing the muscle relaxation associated with the benzodiazepine agonists.

Respiratory effects: Tidal volume and minute ventilation are generally restored to normal with the use of flumazenil following a benzodiazepine; however, the CO_2 response curve of the respiratory center may still depressed (Shalansky et al., 1993). Flumazenil in the absence of a benzodiazepine does not exhibit any respiratory stimulatory effects even at ten times the dose in people (Forster et al., 1993).

Analgesia: Activating or blocking the $GABA_A$ receptor should not affect the pain pathway.

Miscellaneous: Flumazenil does not affect intraocular pressure in health human volunteers when given alone, but does reverse the decrease in intraocular pressure seen after the administration of benzodiazepines (Artru, 1991).

Adverse effects/ contraindications

The use of flumazenil in patients who have been treated chronically with benzodiazepine or have received an overdose of tricyclic antidepressants has the potential of precipitating seizures (Spivey, 1992). This phenomenon of benzodiazepine abstinence syndrome has been seen in dogs experimentally (Lheureux et al., 1992).

To help reduce the pain or discomfort at the injection site, flumazenil may be diluted or administered into a large vein. Extravasation of flumazenil may result in local tissue inflammation and necrosis (Smith and Volmer, 2005).

Metabolism

There is limited information in veterinary species, but in people flumazenil is extensively metabolized by the liver

(99%) to the deethylated free acid and glucuronide conjugate (Klotz, 1988; Schlappi et al., 1988), both of which are excreted in the urine. At least three metabolites have been identified, but none of the metabolites of flumazenil appear to be active (Oliver et al., 2000).

Pharmacokinetics Properties

Although there is pharmacodynamic evidence that flumazenil is effective in veterinary species, there is limited pharmacokinetics information. In humans, the rapid onset of action is due to a rapid uptake and distribution (Klotz and Kanto, 1988). Pharmacokinetic profile in people includes: half-life of 0.7–1.3 hours; apparent distribution volume 0.6–1.6 l/kg; blood clearance of 520–1300 ml/min; and a plasma protein binding of flumazenil of about 40% (Klotz and Kanto, 1988). In dogs, the time for reversal in a model using midazolam-induced respiratory depression with flumazenil was 120 ± 25 seconds IV and up to 310 ± 134 seconds IM (Heniff et al., 1997). Due to the extensive liver metabolism, hepatic diseases can lengthen the elimination phase.

Multiple routes of administration are effective for flumazenil in the dog (IV, IM, sublingual, and per rectal), although the IV route produces the fastest effect (Heniff et al., 1997). Endotracheal administration is also effective in people (Palmer et al., 1998). Despite the fact that flumazenil has a high first-pass effect and the oral route is not recommended (Smith and Volmer, 2005), in dogs it is absorbed after oral administration with peak levels at 1 hour and lasting 4 hours (Wala et al., 1988). However, since benzodiazepine antagonists are generally given due to excessive sedation or side effect, the oral route many not be clinically useful.

Doses

In dogs the dose for benzodiazepine reversal is 0.01–0.04 mg/kg IV, IM, sublingual, endotracheal, or rectal. Repeated doses of flumazenil may be required for the reversal of a benzodiazepine-induced sedation.

In horses, the dose for benzodiazepine reversal is 0.01–0.02 mg/kg IV (Kaegi, 1990; Cornick-Seahorn and Seahorn, 1998).

Regulatory Information

Controlled drug status: Flumazenil in not an FDA scheduled drug.

Withdrawal times: No withdrawal times have been formulated for flumazenil.

Veterinary Approved Products

There are no FDA veterinary approved products.

Veterinary Approved Products Intravenous preparations of flumazenil are 0.1 mg/ml in a 5-ml vial. Each ml contains 0.1 mg of flumazenil and is compounded with 1.8 mg of methylparaben, 0.2 mg of propylparaben, 0.9% sodium chloride, 0.01% edetate disodium, and 0.01% acetic acid. The pH is adjusted to 4 using hydrochloric acid and/or sodium hydroxide.

Overdose/Acute Toxicity

There is limited information on overdoses in veterinary species. However, administration of flumazenil in the absence of benzodiazepines has not produced CNS excitement or tachypnea. Complications associated with accidental overdose or idiosyncratic reaction might be successfully treated with either a benzodiazepine or $GABA_A$ agonist.

Alpha-2-Adrenergic Receptor Agonists

Introduction

Alpha-2-adrenergic agonist drugs are popular in veterinary medicine because they produce profound, reliable sedation as well as analgesia. The first α_2-adrenergic agonist drug used in veterinary medicine was xylazine. It was developed in Germany in 1962 as a human antihypertensive drug (Greene and Thurmon, 1988) but clinical evaluation identified sedation as a potent side effect and the drug was marketed to veterinarians for that use. The veterinary use of α_2-adrenergic agonists was first reported in the late 1960s (Clarke and Hall, 1969), which revolutionized sedation and anesthesia, particularly in large animal patients. Furthermore, α_2-adrenergic agonists act synergistically with opioids so are often used as rescue analgesics. Administration of α_2-agonists can be parenteral, intravenous, intramuscular, and subcutaneous, as well as by transmucosal, transdermal, and neuraxial routes. This class of drug also popular because the effects can be reversed with the use of α_2-adrenergic antagonist drugs (see Section Alpha-**2**-Adrenergic Antagonists).

Classification

The pharmacology of adrenergic agonists and antagonists is covered in Chapter 7. Information on basic pharmacology can be found in that chapter. α_2-adrenergic agonists are sedatives that also possess significant analgesic properties. Although described as α_2-adrenergic receptor agonists, all of the drugs in this category have some agonist effect on α_1-adrenergic receptors, and some will bind and activate imidazole receptors.

Table 14.2 Ratio of drug selectivity and imidazoline receptor activity

Compound	$\alpha_2 : \alpha_1$ selectivity	I_2-Imidazoline activity
Agonists		
Xylazine	160	No
Detomidine	260	Yes
Romifidine	340	Yes
Medetomidine	1620	Yes
Dexmedetomidine	1620	Yes
Antagonists		
Tolazoline		Yes
Yohimbine	40	No
Atipamezole	8526	No

Chemistry

Alpha-2-receptor agonist drugs differ clinically primarily by their differing affinities for α_2 or α_1 adrenergic receptors, also referred to as the $\alpha_2 : \alpha_1$ ratio (Table 14.2). Drugs that are more specific for the α_2-receptor will have a high ratio and the drugs that are less specific for the α_2-receptor will have a lower ratio.

How Supplied

Most α_2-adrenergic agonists used in veterinary medicine are administered parenterally and are dispensed in varying concentrations (see Section Veterinary Approved Products). The veterinary exception is a newly marketed transmucosal gel marketed for horses. The human product, clonidine, is available in oral, ophthalmic, and transdermal patch formulations. Dexmedetomidine is also approved as a human injection (Precedex).

Mechanism of Action

Alpha-2-adrenergic receptors are G-protein receptors and are located both pre- and postsynaptically in the CNS and peripherally. α_2-adrenergic receptors are also located extrasynaptically on the vascular endothelium of vessels as well as on platelets. Furthermore, α_2-adrenergic receptors have been divided into four subtypes (α_{2A}, α_{2B}, α_{2C}, and α_{2D}). Humans express only subtype A–C, whereas some domestic animals, such as cattle, express the D subtype. The presence and percentage of subtypes varies with species, which likely explains the different pharmacodynamic effects and susceptibility among difference species. In general, the α_{2A} subtype is associated with arousal and awareness in the brainstem and the α_{2B} subtype is associated with mediating vasoconstriction. Cattle have a higher percentage of α_{2D} subtypes, which also appear associated with arousal. Although it has been demonstrated that activation of particular subtypes results in different physiological responses (e.g., analgesia or vasoconstriction), none of the current drugs are subtype specific.

The sedative effects of α_2-agonists are mediated by presynaptic binding of α_2-adrenergic receptors supraspinally, in the locus ceruleus of the pons (Scheinin and Schwinn, 1992). Binding of these presynaptic receptors results in a decrease synaptic release of norepinephrine (NE) (Cormack et al., 2005). Norepinephrine is the primary neurotransmitter of the sympathetic nervous system and decrease in NE results in decreased neurotransmission and decreased arousal (sedation).

The analgesic effects of α_2-agonists are primarily mediated in the dorsal horn of the spinal cord via decreased release of NE and substance P. However, there is likely also some descending modulation of nociceptive input via the locus ceruleus (Hellyer et al., 2007).

The α_2-adrenergic agonists also have agonist activity on α_1 and α_2-adrenergic receptors found in vessel vasculature (primarily α_1). Activation of these receptors results in increase in systemic vascular resistance via vasoconstriction of vessels.

The α_2-adrenergic agonists also bind at nonadrenergic imidazoline receptors (Khan et al., 1999). There are at least three subtypes of imidazoline receptors. Imidazoline-1 are associated with central blood pressure control and may contribute to the drugs cardiovascular effects, although the extent and significance is yet to be fully understood (Khan et al., 1999). Additionally, activation of imidazoline-2 receptors may contribute to the analgesic effects (Head and Mayorov, 2006).

Indications

The α_2-adrenergic agonist drugs are used in veterinary patients to provide sedation, chemical restraint, analgesia, and as an adjunct to anesthetics. Some α_2-agonists are also used as emetics, particularly in cats (see Section Gastrointestinal Effects).

Physiological Effects

Central Nervous System Effects

Alpha-2-adrenergic receptors produce profound, reliable sedation in most veterinary species (see Section Mechanism of Action). However, there are differences in response based on species, drug, and dose. The pharmacodynamic differences between species are likely caused by differences in the α_2-adrenergic receptor subtypes in the CNS between species, most notably the presence of α_{2D}-adrenergic receptors in ruminants (Schwartz and Clark, 1998). Ruminants in particular are very sensitive to the sedative effects of certain α_2-adrenergic agonists (e.g., xylazine) in the locus coeruleus nucleus (Scheinin and Schwinn, 1992). Therefore, it is likely that the population of α_{2D}-receptor subtypes in the ruminant CNS is different than other animals.

The duration and depth of the sedation are dose dependent. Lower doses generally produce mild to moderate sedation, where high doses can produce unconsciousness in some species, such as dogs (Kuusela et al., 2001a, 2003). There does appear to be a ceiling effect for sedation in some species, such as horses, where increased doses generally do not result in recumbency, but rather increases the duration of effect.

All currently available α_2-agonist drugs have some α_1 agonist properties. Activation of only α_1-adrenergic receptors in the CNS can cause arousal, agitation, increased locomotor activity, and vigilance (Sinclair, 2003). While excitation is rarely seen, the lack of α_1 activation may contribute to why more selective α_2-agonist drugs generally produce more reliable sedation (see Table 14.2). Rarely, and surprisingly, sedation with α_2-agonists (particularly xylazine, which has the most α_1 effect) in horses can result in aggression (Hubbell and Muir, 2004).

The CNS depression (and analgesia) associated with α_2-agonists produce profound anesthetic-sparing effects (Kuusela et al., 2003; Kauppila et al., 1992; Savola et al., 1991) of both induction agents and MAC sparing of up to 90% (Vickery et al., 1988). It is therefore imperative when using these agents as part of multimodal anesthesia to monitor and adjust other drug doses accordingly.

Intracranial pressure was unchanged in dogs anesthetized with medetomidine (Keegan et al., 1995). Dexmedetomidine in anesthetized dogs was associated with a decrease in cerebral blood flow; however, there was no evidence of ischemia even with the reduced cerebral blood flow (Zornow et al., 1990). Although α_2-agonists are not associated with increased intracranial pressure and cerebral perfusion was maintained, considerations must include the expected decrease in cardiac output, increase in systemic vascular resistance, as well as the potential for hyperglycemia (see Section Glucose). Furthermore, the high incidence of emesis in susceptible small animals also needs to be considered when used in the preoperative period in animals with elevated intracranial pressure. The use of α_2-agonists in patients with CNS disease needs to be assessed on a case to case basis (Cormack et al., 2005).

Cardiovascular Effects

Alpha-2-adrenergic agonists produce a biphasic cardiovascular response. In the "first" phase, activation of presynaptic central α_2-adrenergic receptors reduce the sympathetic outflow (decreased norepinephrine) and thereby increases the parasympathetic tone, which will result in negative inotropic, chronotropic, and dromotropic effects on the heart as well as peripheral vasodilation. High vagal tone and decreased dromotropy often causes first and second-degree atrioventricular heart block. Peripherally, postsynaptic α_2 and α_1-adrenergic receptors are activated in the vascular endothelium causing profound vasoconstriction (which overshadows the vasodilation from the lack of norepinephrine). The increase in arterial blood pressure results in a baroreceptor-mediated reflex bradycardia. Most patients in this first phase are hypertensive and bradycardic. During the "second" phase there is a decrease in systemic vascular resistance (less activation of peripheral vascular adrenergic receptors); however, the heart rate remains low (likely due to decreased norepinephrine). Patients during the second phase may be hypotensive and bradycardic.

At therapeutic doses, α_2-agonists decrease cardiac output in most species by more than 50% (Pypendop and Verstegen, 1998; Lamont et al., 2001; Bueno et al., 1999). Reduction in cardiac output is not only due to the baroreceptor reflex but concomitant reduction in stroke volume, increase afterload, and low catecholamine levels. There appears to be a ceiling effect with the cardiovascular responses to α_2-adrenergic agonists (Kuusela et al., 2000; Pypendop and Verstegen, 1998, 1999). Higher doses produce more sedation, analgesia, and longer duration of action, but do not necessarily worsen the cardiovascular response.

The use of anticholinergics prior to or at the same time as an α_2-adrenergic agonist is controversial. During the first phase, bradycardia is a protective baroreceptor reflex and generally should not be treated. Treatment with anticholinergics only partially prevent the decrease in cardiac output and increase the risk of dysthymia (Sinclair, 2003; Short, 1991) and hypertension (Singh et al., 1997). Hypertension is more likely when the anticholinergic is administered during the initial vasoconstrictive phase than in the secondary hypotensive phase (Pimenta et al., 2011). Arrhythmias are more likely to occur when the anticholinergic is given after the cardiovascular effects (i.e., hypertension and bradycardia) are seen compared with prior to or concurrently with an α_2-agonist (Short, 1991). Arrhythmias associated with α_2-agonists and anticholinergics are likely due to increases in myocardial workload (increased heart rate and increased afterload) and oxygen consumption. α_1-adrenergic receptors have also been implicated in the formation of arrhythmias mediated via α_2-adrenergic agonists, especially with xylazine due to its relatively low $\alpha_2 : \alpha_1$-adrenergic receptor affinity (Bozdogan and Dogan, 1999).

Alpha-2-adrenergic agonists will redistribute blood flow from nonessential regions such as the skin and viscera to the central organs like the brain, heart, and kidneys (Pypendop and Verstegen, 1998; Lawrence et al., 1996). Furthermore, they do not decrease coronary artery perfusion or myocardial oxygenation (Snapir et al., 2006). This may explain why a class of drugs with so many cardiac effects has been shown to improve survivability in human patients undergoing cardiovascular surgery (Wijeysundera et al., 2003).

Respiratory Effects

Alpha-2-adrenergic agonists tend to cause a centrally mediated reduction in respiratory rate and minute ventilation, with no or with mild increases in Paco_2 and mild reductions in Pao_2 (Kolliasbaker et al., 1993; Pypendop and Verstegen, 1999; Sinclair, 2003; Lerche and Muir, 2004). The respiratory depression is not as great compared to other anesthetic drugs such as opioids (Sinclair, 2003) or inhalational anesthetics (Bloor et al., 1989). Respiratory depression is exaggerated with the addition of other respiratory depressants or CNS depressants, which can result in hypercapnia, hypoxemia, and cyanosis (Pypendop and Verstegen, 1999). It is speculated that cyanosis of mouth and gums may also be due to slower blood flow through the peripheral capillary beds and an increased oxygen extraction (Sinclair, 2003). It is therefore recommended to monitor patients for hypoventilation and hypoxemia and administer supplemental oxygen as needed, especially in those receiving a combination of respiratory depressants.

Serious, species-specific, respiratory side effects caused by α_2-adrenergic agonists can occur (Bloor et al., 1989; Celly et al., 1997). The most noted complication occurs in sheep. Within minutes of α_2-adrenergic agonist administration in sheep there can be activation of pulmonary intravascular macrophages (PIM) that produce extensive damage to the capillary endothelium and alveolar type I cells, intraalveolar hemorrhage, and interstitial and alveolar edema (Celly et al., 1997). Pulmonary edema causes decreased alveolar gas exchange, an increase in respiratory rate and airway pressures, and a decrease in pulmonary compliance. Hypoxemia is frequently observed and some sheep will die (Celly et al., 1997). While many animal species (e.g., horses) have PIMs, the activation of these by α_2-agonists in sheep is more commonly seen clinically. Dexmedetomidine causes similar pulmonary changes in the sheep and goat (Kutter et al., 2006). Treatment with an α_2-adrenergic antagonists appears to prevent further activation of PIMs, reverses sedation, and many animals improve clinically. However, the pulmonary effects are not completely eliminated with reversal.

Musculoskeletal Effects

Alpha-2-adrenergic agonists produce reliable muscle relaxation, which is mediated via their interaction with the interneurons in the spinal cord (Sinclair, 2003). They are frequently administered for this effect and to balance drugs that do not provide good muscle relaxation (e.g., ketamine). Muscle twitching has been noted in the dog (Sinclair, 2003) and head bobbing and facial twitching has also been observed in the horse (Lloyd Industries, 2014).

Alpha-2-agonist drugs can effect muscle tone and contraction of smooth muscle such as the uterus and GI tract (see Sections Gastrointestinal Effects and Reproductive Effects).

Gastrointestinal Effects

Emesis: Alpha-2-adrenergic agonist (xylazine) may cause vomiting in up to 90% of cats and 30% of dogs (Cullen, 1999). It has been theorized that α_2-agonists interact with the chemoreceptor zone located in the area postrema to stimulate dopamine and norepinephrine receptors to cause emesis. This appears to be a postsynaptic α_2-adrenergic receptor mediated event, which can be antagonized by α_2-antagonist drugs (Jovanovic-Micic et al., 1995).

Motility and acid secretion: Alpha-2-agonists decrease gastrointestinal motility, prolong intestinal transit time, and inhibit colonic motility in a number of species, with the large bowel more sensitive to the effects of α_2-adrenergic agonists in ruminants, dogs, and horses (Sasaki et al., 2000; Maugeri et al., 1994). The depression in gastrointestinal motility can be attenuated with the use of an α_2-antagonist. α_2-agonists also decrease gastric acid secretions. The effects on intestinal motility must be considered when these drugs are used to sedate animals undergoing diagnostic tests of intestinal function. This should also be considered when administered to animals prone to complications from ileus (e.g., horses).

Renal effects

Alpha-2-adrenergic agonists cause diuresis by multiple mechanisms. They reduce the production or release of antidiuretic hormone (ADH, arginine vasopressin) from the pituitary (Humphreys et al., 1975; Reid et al., 1979); inhibit the actions of ADH on the collecting tubules; and enhance the excretion of sodium (Gellai and Edwards, 1988; Smyth et al., 1985). Renin levels are decreased by the direct activation of renal α_2-adrenergic receptors and indirectly by the initial hypertension produced by the α_2-adrenergic agonists (Smyth et al., 1987) further contributing to diuresis.

Alpha-2-adrenergic agonists also affect micturition by decreasing micturition pressure, bladder capacity, micturition volume, and residual volume via both spinal and peripherally mediated mechanism (Ishizuka et al., 1996). This, combined with diuresis, will cause animals treated with α_2-agonists to produce large amounts of dilute urine that is frequently voided.

Neuroendocrine Stress Response

Predicting the effects of α_2-adrenergic agonists on catecholamines and cortisol levels is difficult. In general, α_2-adrenergic agonists will decrease catecholamine due to their presynaptic effects on the release of norepinephrine. However, the effects on basal or induced cortisol varies based on drug, dose, and species. In the horse, detomidine will suppress catecholamine activity without suppressing cortisol activity (Raekallio, 1991) whereas in cattle, medetomidine will suppress catecholamine activity without suppressing cortisol activity (Ranheim, 2000). Interestingly, in the dog, high doses (80 μg/kg) of dexmedetomidine suppressed cortisol levels as well as prevented stimulation with ACTH (Maze et al., 1991). However, at clinical doses, dexmedetomidine did not change cortisol level in dogs (Restitutti et al., 2012).

Glucose

The effect of α_2-adrenergic agonists on glucose homeostasis is complex and dependent upon the drug, the dose, and the species. Hyperglycemia reported after the use of α_2-adrenergic agonists is likely due to a decrease in insulin release from the β-cells in the pancreas and/or increase glucagon release from the α-cells (increased gluconeogenesis) (Angel et al., 1990; Niddam et al., 1990). The α_2-adrenergic agonist, xylazine, causes a mild transient hyperglycemia in cows and horses (Thurmon et al., 1984; Hsu and Hummel, 1981). Medetomidine causes a decrease in insulin without the resultant increase in glucose in dogs (Ambrisko and Hikasa, 2003). Clinical hyperglycemia secondary to α_2-adrenergic agonist administration is generally not high enough to pass the renal threshold for glucose (~180 mg/dl) and therefore should not produce glucosuria.

Reproductive Effects

Alpha-2-agonist drugs can effect myometrial tone as well as myometrial contraction; however, these effects are related to species, dose, time of reproductive cycle, and species. Furthermore, the clinical effect of α_2-adrenergic agonists on uterine contractility and blood flow is influenced by the level of estrogen and progesterone. Estrogen leads to an up-regulation in α-adrenergic receptors while progesterone will cause a down-regulation due to changes in the transmembrane signal pathways that cause the differences in myometrial contractility (Re et al., 2002).

Myometrial contractions in the nongravid uterus were observed at any equipotent dose of α_2-adrenergic agonists (Schatzmann et al., 1994; Jedruch et al., 1989) and there is a case report of cows having premature labor after the administration of xylazine (Vanmetre, 1992). Lower doses of detomidine (<60 μg/kg IM) in the cow and horse, and medetomidine (<20 μg/kg IV) in the dog, decreased myometrial contractions (Jedruch and Gajewski, 1986; Jedruch et al., 1988, 1989). Higher doses of medetomidine in the dog did cause an increase in myometrial contraction (Jedruch et al., 1989). This biphasic response in the gravid uterus to α_2-adrenergic agonists may possibly be mediated by their effect on the α_1-adrenergic receptor (Ford, 1995; Gaspar et al., 2001; Jedruch et al., 1989).

The effects of medetomidine (40 μg/kg IM) and xylazine (200 μg/kg IM) on intrauterine pressure and uterine blood flow have been studied in the goat (Sakamoto et al., 1996, 1997). Both agents crossed the placenta, reduced uterine blood flow for 120 minutes, and increased intrauterine pressure. These observations would suggest α_2-adrenergic agents should be used with caution in near-term pregnant animals, especially if there are historical or physical evidence to suggest fetal distress is already present.

Miscellaneous

Thermoregulation: Patients may be unable to normally control body temperature in response to the administration of α_2-adrenergic agonists. This is due to the combination of CNS depression, reduction in muscle activity (reduction in shivering), and loss of vasomotor control. Clonidine and dexmedetomidine have been shown to decrease the vasoconstrictive and shivering thresholds (Talke et al., 1997). Animals may be cool to touch and unable to thermoregulate their body temperature. Care must be taken during the recovery phase to prevent both cooling and overheating of these animals.

Equine recovery: The use of α_2-adrenergic agonists during the postoperative period following inhalant anesthesia of horses has been shown to improve the quality of the recovery and reduce the number of attempts to stand, at the expense of slightly prolonging the recovery period (Bienert et al., 2003; Santos et al., 2003). The dose of α_2-adrenergic agonists used during this postanesthesia period may be as little as 10–20% of the "usual" premedication dose (Santos et al., 2003). Romifidine when used as a premedicant only exhibited a better quality of recovery as compared to xylazine (Jaugstetter et al., 2002), although recovery quality must be assessed in relation to the other anesthetic drugs administered, procedure performed, and recovery environment. The use of intraoperative constant rate infusions of medetomidine and romifidine have been shown to improve the quality of the recovery in horses with fewer attempts to stand (Kuhn et al., 2004).

Platelet activation: At very high doses, α_2-adrenergic agonists enhance catecholamine-potentiated platelet aggregation (Sjoholm et al., 1992). The clinical consequences of this reaction has not been documented.

Analgesia

Alpha-2-agonists produce profound analgesia and can be administered parenterally and neuraxially (e.g., epidurally). The first report of α_2-adrenergic agonist-induced analgesia was in 1974 evaluating clonidine as an analgesic in rats (Paalzow, 1974). Analgesia is produced by activation of α_2-receptors in the CNS in the locus coeruleus (Guo et al., 1996; Schwartz and Clark, 1998) and in the substantia gelatinosa of the dorsal horn of the spinal cord (Savola and Savola, 1996). The effects in the brain are primarily by decreased neural conduction, whereas the effects in the spinal cord are primarily through decreasing release of norepinephrine and substance P (see Section Mechanism of Action). Some of the analgesia may be mediated via I_2-imidazoline receptors (Diaz et al., 1997; Regunathan, 2006) as imidazoline receptor agonist and antagonists can modulate the analgesia produced by morphine (Gentili et al., 2006).

The analgesia produced by α_2-agonists is synergistic with opioids, lidocaine, and *N*-methyl-D-aspartate (NMDA) receptor antagonists (e.g., ketamine) (Glynn and O'Sullivan, 1996; Lee and Yaksh, 1995; Regunathan, 2006). Therefore these drugs are often used in conjunction with other analgesics.

In people with tolerance to opioids or chronic pain syndromes, α_2-adrenergic agonists are routinely used for rescue analgesia. A major limiting factor to use of this class for analgesia is the concurrent sedation and ataxia. Interestingly, higher plasma levels are needed to produce analgesia than sedation, with horses needing 10 times the plasma level to produce visceral nociception compared with plasma levels needed to produce sedation (Elfenbein et al., 2009).

Epidural administration can produce potent analgesia with minimal sedative or cardiovascular effects compared with intravenous administration (Aminkov and Pascalev, 1998; Greene et al., 1995). The primary receptor subtypes found in the spinal cord are α_{2A} and α_{2C}, but α_{2A}-receptors appears to most active in the nociceptive pathway (Stone et al., 1998). Due to the high lipophilicity of these drugs, there is some systemic absorption and systemic effect (e.g., sedation) after neuraxial administration. The use of α_2-adrenergic antagonists following neuraxially administered α_2-agonists can reduce the side effects whilst maintaining a good level of analgesia (Skarda, 1991).

Clinicians should also note that when α_2-agonist reversal agents are administered (α_2-antagonists; see Section Alpha-2-Adrenergic Antagonists), to reverse sedation, the analgesic effects will be reversed also.

Pharmacokinetics Properties

Pharmacokinetics of α_2-agonist can vary based on species, drugs, and dose. In general, the onset of action of most α_2-adrenergic agonists following intravenous administration is rapid (within minutes) and peak effect usually occurs within 10–15 minutes (Garcia-Villar et al., 1981; Pypendop and Verstegen, 1998). Intramuscular administration of α_2-adrenergic agonists will approximately double the time to peak effect; however, the bioavailability is variable (40–95%) depending upon the species (Garcia-Villar et al., 1981; Kästner et al., 2003). Bioavailability of intramuscular xylazine in the horse and sheep is approximately 50% as compared to 75% in the dog (Garcia-Villar et al., 1981). Bioavailability of intramuscular detomidine is variable depending on species: horse 66%, and cow 85%(Salonen, 1989). Bioavailability of intramuscular medetomidine is close to 100% in dogs and cats (Salonen, 1989). The pharmacokinetic parameters of the various α_2-adrenergic agonists in the common domestic species are summarized in Table 14.3.

Interestingly, there is a lack of correlation between plasma levels and pharmacodynamic effects of medetomidine in cows and sheep (Ranheim et al., 1999, 2000). Clinical effects can be seen for up to 7 hours despite the plasma levels being detectable for only 2 hours. This discrepancy implies either a long tissue binding period or an active metabolite (Ranheim et al., 1999, 2000).

Comparative Equine Doses and Effects

Equipotent intravenous doses for sedation in the horse are considered to be the following: xylazine (1 mg/kg), medetomidine (5–10 μg/kg), romifidine (40–80 μg/kg), and detomidine (20–40 μg/kg) (England et al., 1992; Yamashita et al., 2002). The order in which they are listed also demonstrates the duration of sedation from the shortest to longest in duration (Freeman and England, 2000; Hamm et al., 1995; Yamashita et al., 2002). Detomidine tends to cause the longest duration of ataxia (Hamm et al., 1995; England et al., 1992). There appears to be less ataxia and lowering of the head with romifidine as compared to the other α_2-adrenergic agonists; however, the level of analgesia achieve may be comparable to (England et al., 1992; Spadavecchia et al., 2005) or lower than (Moens et al., 2003; Hamm et al., 1995) other α_2-adrenergic agonists, depending upon the stimulus used. The apparent order of ataxia in horses produced by these agents from least to most appears to be: romifidine < xylazine < medetomidine and detomidine.

Specific Veterinary Drugs

Xylazine hydrochloride

Synonyms: Rompun AnaSed, Cervizine.

Molecular formula: C12-H16-N2-S (Figure 14.5).

Molecular weight: 220.338 g/mol.

Table 14.3 Alpha-2-adrenergic agonists pharmacokinetics

Drug	Species	Dose (mg/kg)	Mean Residence Time (minutes)	Volume of distribution (L/kg)	$\text{Clearance}_{\text{Tot}}$ (mL/kg/min)	Elimination half-life (mins)	Reference

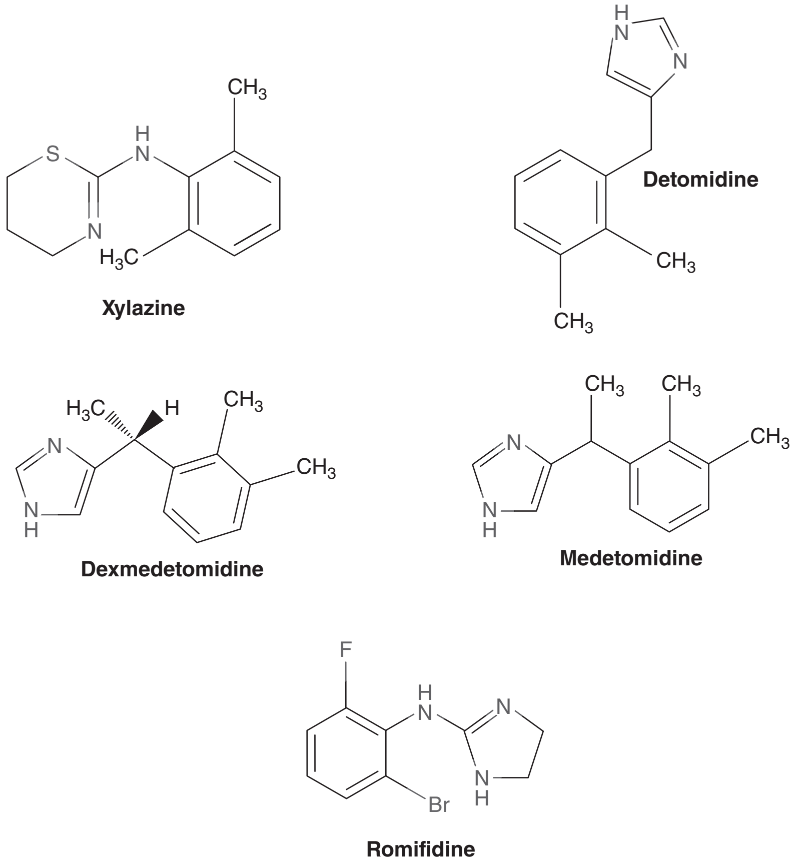

Figure 14.5 Alpha-2-agonists.

Systematic chemical name: N-(2,6-dimethylphenyl)-5,6-dihydro-4H-1,3-thiazin-2-amine (XX).

Xylazine was the first α_2-adrenergic agonists used in veterinary medicine and its clinical use was first described in the 1969 in a number of species (Clarke and Hall, 1969; Keller, 1969; Müller et al., 1969). Xylazine is often thought of as the prototypical α_2-adrenergic agonist; however, it does have one of the lowest $\alpha_2 : \alpha_1$ affinities (Table 14.2), and does not bind to imidazoline receptors. It is still the most commonly used α_2-agonist in horses and is also commonly used in lab animal and wildlife medicine. Interestingly, although rare, xylazine has been associated with aggressive behavior following administration in horses (Hubbell and Muir, 2004), which may be due to the excitatory effects of α_1-agonists in the CNS (see Section Central Nervous System Effects).

Cattle are particularly sensitive to the effects of xylazine and require a much reduced dose compared with other species and approximately one-tenth the dose compared with horses. The dose rate of other α_2-adrenergic agonists in cattle is similar to other species. Conversely, swine require two to three times the dose of xylazine compared to the dog, cat, or horse. These species differences are likely due to differences in G-protein signaling pathways (Törneke et al., 2003), as well as anatomical differences in α_2 and α_1-receptor distributions (Hellyer et al., 2003). Xylazine is the α_2-agonist most likely to cause vomiting in the dog, whereas almost all α_2-agonists cause vomiting in cats (Jovanovic-Micic et al., 1995; Sinclair, 2003).

Dosage

See Box 14.5.

Box 14.5 **Xylazine dosages**

Species	Dose and route
Dog and cat	0.1–1.0 mg/kg IV, IM
Cat emesis	0.4–0.5 mg/kg IV
Horse	0.02–1.0 mg/kg IV, IM
Bovine	0.01–0.1 mg/kg IV, IM
Ovine and caprine[a]	0.05–0.3 mg/kg IV, IM
Cervidae (deer)	0.5–4.0 mg/kg IM

[a] Xylazine can induce respiratory distress (see respiratory effects)

How supplied: Each ml of xylazine hydrochloride is equivalent to 20, 100, or 300 mg of base activity, methylparaben 0.9 mg, propylparaben 0.1 mg, sodium citrate dihydrate 5.0 mg and water for injection. pH adjusted with citric acid and sodium citrate.

Regulatory Information

Controlled drug status: Nonscheduled drug.

Withdrawal times:

Cattle: Milk withholding time is 24 hour; slaughter withdrawal time is 4 days.
Cervidae: Not approved for use during hunting season.

Veterinary Approved Products (Representative)

Xylazine is approved by the FDA for use in the dog, cat, horse, and deer.

Rompun® Injectable: xylazine HCl, 20 and 100 mg/ml (Bayer Healthcare, Animal Health Division)
AnaSed® Injectable: xylazine HCl, 20 and 100 mg/ml (Lloyd, Inc.)
Cervizine 300 Injectable: xylazine HCl, 300 mg/ml (Lloyd, Inc.)

Detomidine Hydrochloride

Synonym: Dormosedan.

Molecular formula: C12H14N2.HCl (Figure 14.5).

Molecular weight: 222.7 g/mol.

Systematic chemical name: 1H imidazole, 4-[(2,3-dimethylphenyl) methyl]-hydrochloride.

It is a white, crystalline, water-soluble substance. Detomidine is FDA approved only for use in the horse; however, it is used in bovines and to a lesser degree in small ruminants (Singh et al., 1989, 1997). It has a higher $\alpha_2 : \alpha_1$ ratio than xylazine (Table 14.2), and in horses, detomidine has the longest duration of action (Yamashita et al., 2000) and results in the longest duration of ataxia (England et al., 1992; Hamm et al., 1995). Although the pharmacodynamic effects of the various α_2-agonists at equipotent doses have been reported to be similar, except for the duration of action (Bueno et al., 1999; England et al., 1992), most clinicians believe that, in horses, detomidine provides more profound sedation and less weight shifting when sedated then other α_2-adrenergic agonists.

Detomidine was one of the first α_2-adrenergic agonists to be administered as a constant rate infusion in horses for standing surgical procedures (Daunt et al., 1993; Wilson et al., 2002). Horses sedated via constant rate infusion assume a base-wide stance and with appropriate local blocks will tolerate significant surgical manipulation.

Oral/transmucosal administration of injectable detomidine has been used with varying degrees of success in the number of species (Pollock and Ramsay, 2003; Ramsay et al., 2002; Sleeman and Gaynor, 2000; Grove and Ramsay, 2000). A combination of detomidine and ketamine administered orally in the cat proved more effective than a combination of ketamine and xylazine or medetomidine (Grove and Ramsay, 2000). Oral detomidine in the horse produced maximal sedation 30 minutes postadministration (Ramsay, 2002).

Detomidine Gel is a transmucosal product licensed for use in horses only. The bioavailability in horses is ~22% (Kaukinen et al., 2011), and effective sedation reached in the majority of horses 40 minutes after administration (Gardner et al., 2010). Detomidine gel has also been successfully used off label in dogs and ferrets (Hopfensperger et al., 2013; Phillips et al., 2015). The transmucosal gel, when applied to the oral mucosa of dogs in a small volume produces sedation or recumbency (depending on the dose) that has an onset of approximately 30–45 minutes, with a duration in dogs of approximately 90 minutes.

Dose

See Box 14.6.

Box 14.6 Detomidine dosages

Species	Dose and route	Reference
Horse	Parenteral: 5 – 40 μg/kg IV, IM CRI: Loading bolus 8.4 μg/kg IV 1st 15 min. 0.5 μg/kg/min IV 2nd 15 min 0.3 μg/kg/min IV 3rd 15 min 0.1 μg/kg/min IV Transmucosal Gel: 40 μg/kg between gum and cheek, or under tongue	
Cat	Oral: 500 μg/kg detomidine + 10 mg/kg ketamine	(Grove and Ramsay, 2000)
Dog	Transmucosal Gel: mild sedation 0.5 mg/m^2; higher sedation and lateral recumbency: 1.0 mg/m^2. (Average dose is 35 μg/kg.) A high dose of 2–4 mg/m^2 will produce more profound sedation. (Using the 7.6 mg/ml: Dormosedan Gel)	
Ferret	Transmucosal Gel: 2 mg/m^2 and 4 mg/m^2 (transmucosal) (Using the 7.6 mg/ml: Dormosedan Gel)	(Phillips et al., 2015)

How supplied: Each ml of detomidine has 10 mg/ml.

Veterinary Approved Products
Approved for use in horses

Liquid for injection, 10 mg/ml, Dormosedan (Zoetis, USA).
Gel for transmucosal application, 7.6 mg/ml, Dormosedan Gel (Zoetis, USA).

Regulatory information

Controlled drug status: Nonscheduled drug.

Withdrawal times: Not approved for use in horses intended for human consumption.

Extralabel use in cattle: 3 days meat, 72 hours milk.

Romifidine

Synonym: Sedivet.

Molecular formula: C9-H9-Br-F-N3 (Figure 14.5).

Molecular weight: 258.093.

Chemical name: 2-(2-Bromo-6-fluoroanilino)-2-imidazoline.

Romifidine is a more selective α_2-agonist than xylazine (Table 14.2) and in the horse produces less ataxia compared with equipotent doses of other α_2-adrenergic agonists (England et al., 1992). Romifidine improved the quality of recovery in horses when given preoperatively (Jaugstetter et al., 2002) or postoperatively (Woodhouse et al., 2013), which may reflect the longer duration of action of romifidine compared to xylazine or less ataxia, or both.

Romifidine causes similar cardiovascular depression in the cat (Selmi et al., 2004) and dog (Pypendop and Verstegen, 2001). There is a ceiling effect with respect to the cardiovascular changes induced by romifidine in the dog and horse (Pypendop and Verstegen, 2001; Freeman et al., 2002). A similar ceiling effect was reached for the level of sedation in the dog (<25–40 μg/kg IV) (Pypendop and Verstegen, 2001).

The amount of analgesia romifidine produces in the horse is controversial with some researchers finding no analgesic effects (Hamm et al., 1995), while others have documented analgesia (Moens et al., 2003; Spadavecchia et al., 2005). Neuraxial romifidine potentiates the effects of epidural morphine and lidocaine in cattle and goats (Fierheller et al., 2004; Kinjavdekar et al., 2003).

Doses
See Box 14.7. Romifidine is only approved for use in horses.

Box 14.7 Romifidine dosages

Species	Dose and route
Horse	40–120 μg/kg IV
Dog	1–40 μg/kg IV
Cat	5–200 μg/kg IM

Regulatory information

Controlled drug status: Nonscheduled drug.

Withdrawal times: Not approved for use in horses intended for human consumption.

Veterinary Approved Products
Romifidine is approved by the FDA for use in the horse.

Sedivet® 1% Injection, Romifidine HCl 10 mg/ml (Boehringer Ingelheim Vetmedica, Inc.).

Medetomidine and Dexmedetomidine
Medetomidine is a racemic mixture of two optical enantiomers, dexmedetomidine and levomedetomidine (1 : 1). The structures of these two enantiomers are mirror images of each other, but they each possess different biological activity. Both drugs have been or are marketed in the veterinary community.

Medetomidine

Synonym: Domitor.

Molecular weight: 200.283.

Molecular formula: C13-H16-N2 (Figure 14.5).

Chemical name: 4-[1-(2,3-dimethylphenyl)ethyl].

Medetomidine is a racemic mixture of two optical enantiomers, dexmedetomidine and levomedetomidine (1:1). The active component of medetomidine is dexmedetomidine; however, medetomidine does not appear to have simply half the potency of dexmedetomidine (Kuusela et al., 2000, 2001b). Levomedetomidine has minimal behavioral effect but likely contributes to the cardiovascular effects (Kuusela et al., 2000, 2001b).

Medetomidine produces profound reliable sedation and analgesia. Medetomidine is also used frequently to treat emergence delirium following anesthesia, particularly in patients with awakening from painful surgical procedures. Microdoses of 1–2 μg/kg are usually sufficient to quiet a patient and allow it to rest comfortably. Similarly, constant rate infusions of medetomidine are popular in the ICU setting to provide similar sedation, anxiolysis, and analgesia.

Dose

See Box 14.8.

Box 14.8 Medetomidine dosages

Species	Dose and route
Dogs	Single injection: 1–20 μg/kg IV, IM Constant rate infusion: 1–5 μg/kg/hour
Cats	Single injection: 1–40 μg/kg IV, IM Constant rate infusion: 1–5 μg/kg/hour
Horse	Single injection: 2–10 μg/kg IV, IM Constant rate infusion: 0.03–0.1 μg/kg/min

Veterinary Approved Products

Medetomidine is approved by the FDA for use in the dog.

Domitor®: Medetomidine HCl 1 mg/ml (Orion Corp.).

Regulatory Information

Controlled drug status: Nonscheduled drug.

Withdrawal times: Not approved for use in food-producing animals.

Dexmedetomidine

Synonyms: Dexdomitor, Precedex.

Molecular weight: 200.283.

Molecular formula: C13-H16-N2 (Figure 14.5).

Chemical name: 4-[(1R)-1-(2,3-dimethylphenyl)ethyl].

Dexmedetomidine is the dextro-enantiomer of the racemic drug, medetomidine. It was originally marketed for people (Precedex), but it is approved for use in dogs and cats in the USA. Since the dextro-enantiomer is the biological active form, it was assumed this form would need half the dose and produce less side effects than the racemic mixture of medetomidine. However, there appears to be a complex interaction between the dextro-enantiomer and levo-enantiomer to produce the pharmacodynamic effects of the racemic mixture of medetomidine (Kuusela et al., 2000, 2001b); therefore dosing is generally a little more than half the dose of medetomidine's expected effects. Clinically, at equipotent doses, sedation, analgesia, and cardiovascular effects are similar to medetomidine (Kuusela, 2004).

Representative Dosages

See Box 14.9.

Box 14.9 Dexmedetomidine dosages

Species	Dose and route
Dog	Single injection: 0.5–10 μg/kg IM, IV Constant rate infusion: 0.5–3.0 μg/kg/h IV
Cat	Single injection: 1–20 μg/kg IM, IV Constant rate infusion: 0.5–3.0 μg/kg/h IV

Veterinary Approved Products

Dexmedetomidine is approved by the FDA for use in the dogs and cats.

Dexdomitor®: Dexmedetomidine HCl, 0.1 mg/ml and 0.5 mg/ml (Zoetis).
Human formulation is Precedex®, 4 or 100 μg/ml.

Regulatory Information

Controlled drug status: Nonscheduled drug.

Withdrawal times: Not approved for use in food-producing animals.

Species Differences

There are species differences to the sedative effects of α_2-adrenergic agonists. In general, from the most sensitive to least sensitive are: bovine > camelids > small ruminants > cat, dog, and horse > porcine > small laboratory animals.

Cattle: Ruminants generally have an exaggerated response to the sedative effects of α_2-agonists and, in particular, xylazine. It has been suggested that cattle may have some central α_1-receptors that contribute to sedation, or this may be due to them having an α_{2D}-adrenergic receptors (Schwartz and Clark, 1998). In particular, cattle need ~1/10 the dose of xylazine compared with horses.

Sheep: Xylazine causes the activation of pulmonary intravascular macrophages (PIM), which results in acute lung injury (see Section Respiratory Effects).

Horse: Equipotent intravenous doses for sedation in the horse are considered to be the following: xylazine (1 mg/kg), medetomidine (5–10 μg/kg), romifidine (40–80 μg/kg), and detomidine (20–40 μg/kg) (England et al., 1992; Yamashita et al., 2002; Bryant et al., 1991).

Adverse effects/ contraindications

Alpha-2-adrenergic agonists should not be used in animals with compromised cardiac output, such as preexisting heart disease, especially those with bradydysrhythmia, poor myocardial contractility, obstructive valvular disease, dehydration, hypovolemia, or sepsis.

It is possible to see sudden arousal from α_2-adrenergic agonist-induced sedation that may proceed to aggression. This may be due to sensitivity to sound and or touch as well as the excitatory effects of α_1-receptors in the CNS (Clarke and Hall, 1969; Hubbell and Muir, 2004).

Caution should also be used in patients with diabetes mellitus (see Section Glucose).

Drug Interactions

Alpha-2-adrenergic agonists potentiate the CNS depressant effects of other sedative agents such as propofol, ketamine, or opioids. The dosage of induction agents is greatly reduced and there is a profound MAC-sparing effect. The respiratory depression of α_2-adrenergic agonists is potentiated by other respiratory depressant, especially opioids. This combination is more likely to cause hypercapnia and hypoxemia compared to α_2-adrenergic agonists alone.

Overdose/Acute Toxicity

Treatment for the overdose of an α_2-adrenergic agonist is centered on the use of α_2-adrenergic antagonists titrated to effect (e.g., atipamezole or yohimbine, see Sections Atipamezole and Yohimbine). Careful monitoring of the cardiovascular and respiratory systems is required. Other supportive therapy may include external regulation of body temperature and monitoring of blood glucose levels.

Alpha-2-Adrenergic Antagonists

History/ Introduction

Alpha-2-adrenergic receptor antagonists are used primarily in veterinary medicine to reverse the wanted or unwanted effects of the α_2-adrenergic agonists. The ability to reverse the α_2-adrenergic agonists increases their appeal for use in general veterinary medicine as well as their use for the chemical restraint for zoo animals and exotic wildlife. Three antagonists are available for use in veterinary medicine: atipamezole, yohimbine, and tolazoline.

Classification

Drugs in this class are all α_2-adrenergic receptor ligands that are competitive antagonist at the α_2-adrenergic receptor site. They all have varying degrees of antagonism at the α_1-adrenergic receptor site as well.

Mechanism of Action

Alpha-2-adrenergic antagonist drugs act by competitively binding to the α_2-adrenergic receptor and preventing activation. Like α_2-adrenergic receptor agonists, antagonists vary by their selectivity of binding α_2 or α_1-adrenergic receptors. Binding without activation reverses and/or attenuates the sedation, anxiolysis, analgesia, and the central and peripheral cardiovascular changes induced by α_2-adrenergic agonists; however, behavioral and cardiovascular effects vary by species and drug (Carroll et al., 2005; Hubbell and Muir, 2006).

Indications

Alpha-2-receptor antagonists are routinely used to reverse the sedative or physiological (cardiovascular or respiratory) effects of α_2-agonist drugs. It is logical and generally recommended to choose an antagonist with a similar specificity as the agonist given. For example, xylazine is commonly reversed with yohimbine and dexmedetomidine is reversed with atipamezole; however, reversal can and does occur with more or less specific reversal agents. Some species differences do exist (see Section Specific Drugs).

Dosages for full reversals are given below. However, many clinicians routinely give antagonists at lower doses since some of the α_2-agonist has already been metabolized and leaving some sedative and analgesic effects results in a less excited return to function.

Reversal of Analgesia

Abrupt and compete reversal of α_2-adrenergic agonist drugs may lead to a sudden increase in sympathetic activity and nociception (reversal of analgesia) that at a minimum may be unpleasant and, at worst, inhumane. In various animal studies, the use of atipamezole to reverse the effects of α_2-adrenergic agonists increased the nociceptive response by blocking the norepinephrine feedback inhibition of pain sensation (Pertovaara et al., 2005). Following α_2-receptor antagonism, patients need to be assessed for pain levels and may be administered other analgesic such as opioids or nonsteroidal antiinflammatory drugs (NSAIDs).

Specific drugs

Atipamezole

Synonyms: Antisedan, Atipamezol, Atipamezolum.

Molecular weight: 212.294.

Molecular formula: C14-H16-N2 (Figure 14.6).

Chemical name: 4-(2-ethyl-1,3-dihydroinden-2-yl)-3H-imidazole.

Atipamezole is a highly specific α_2-receptor antagonist that was designed to reverse the effects of medetomidine and dexmedetomidine. It is approved only for intramuscular use in dogs, but is commonly used off label in cats, horses, and exotic species. Along with its high specificity for the α_2-receptor, atipamezole does not bind at β-adrenergic, 5-HT, histaminergic, muscarinic, or dopaminergic receptors, which decreases side effects with administration(Tranquilli et al., 2007).

Atipamezole acts rapidly, producing shorter reversal time for lambs sedated with medetomidine 30 μg/kg IV as compared to yohimbine (Ko and McGrath, 1995), allowing the lambs to walk within 2–3 minutes as compare 15 minutes. However, there are various reports of atipamezole not providing full reversal in horses administered the less specific drug detomidine (Zeiler, 2015), therefore some animals require repeated dosing to get a full reversal and some animal can become resedated later.

Aside from their use as reversals, α_2-antagonists have been used as therapeutics. Atipamezole has also been used to reverse the toxic effects of amitraz poisoning in the dog (Hugnet et al., 1996) and cat (Andrade et al., 2006). Since I_2-imidazoline receptors are involved in the pathogenesis of Parkinson's disease (Gentili et al., 2006), there are ongoing efforts investigating the uses of atipamezole in cognitive enhancement functions (nootropic), brain injury, and as a potential antiparkinsonian therapy (Pertovaara et al., 2005). Yohimbine is used to treat erectile dysfunction in men, but there is no record of this use in veterinary medicine.

Representative Dosage

Atipamezole is approved for IM use in dogs only (Box 14.10). The product label for atipamezole lists the dosage in μg/m^2 (see below). However, many veterinarians administer atipamezole at an equal volume (ml) to the amount of medetomidine/ dexmedetomidine given (1.0 mg/ml and 0.5 mg/ml, respectively). Given each drug's concentration, this is equivalent to reversing with five times the concentration of medetomidine/ dexmedetomidine.

Box 14.10 Atipamezole dosages

Species	Dose and route
Dogs	Reversal of α_2-agonist: 3750 μg/m^2 IM (product label dosage)
	Reversal of α_2-agonist: 0.1–0.3 mg/kg IM
Cats	Reversal of α_2-agonist: 0.1–0.3 mg/kg IM
Horses	Reversal of α_2-agonist: 0.03–0.06 μg/kg IV, IM

Veterinary Approved Products

Atipamezole HCL: Antisedan®, 5 mg/ml (Zoetis).

Regulatory Information

Controlled drug status: Nonscheduled drug.

Withdrawal times: Not approved for use in food-producing animals.

Yohimbine

Synonyms: Yobine, Antagonil, Yohimbin.

Molecular formula: C21-H26-N2-O3 (Figure 14.6).

Chemical name: Yohimban-16-alpha-carboxylic acid, 17-alpha-hydroxy-, methyl ester.

Yohimbine is an indole alkaloid that is derived from the bark of the *Pausinystalia yohimbe* tree or the root of the *Rauwolfia serpentina* plant. It is a nonselective α_2-receptor antagonist and at high doses can activate α_1-adrenoreceptors, dopamine and serotonin receptors, and inhibit monoamine oxidase production (DiMaio Knych et al., 2011). It is approved for use in dogs and cervidae, but is commonly used to reverse the effects of the α_2-agonist xylazine in dogs, cats, horse, cattle, and exotic species. Pharmacokinetic data for various species are summarized in Table 14.4. Rapid IV administration can result in hypotension from vasodilation as well as CNS excitement. Clinicians will often administer a fraction (25–25%) of the dose IV and the remainder IM, to help prevented unwanted side effects.

Yohimbine is classified as a Class 2 foreign substance by the Association of Racing Commissioners International (ARCI) (DiMaio Knych et al., 2011).

Yohimbine has been used in human medicine to treat erectile dysfunction (Riley, 1993).

Representative Dosages

See Box 14.11.

Box 14.11 Yohimbine dosages

Species	Dose and route
Dogs and cats	Reversal of α_2-agonist: 0.11 mg/kg IV; 0.25–0.5 mg/kg IM
Horses	Reversal of α_2-agonist: 0.02–0.075 mg/kg IV
Cattle and sheep	Reversal of α_2-agonist: 0.125–0.2 mg/kg IV

Veterinary Approved Products

Yohimbine is approved by the FDA for use in the dog and cervidae (elk and deer).

Yobine® Injectable Solution: Yohimbine HCl, 2.0 mg/ml (Akorn, Inc.).
Antagonil®: Yohimbine, HCl 5.0 mg/ml (Wildlife Laboratories, Inc.).

Regulatory Information

Controlled Drug Status: Nonscheduled drug.

Withdrawal times: Not approved for use in food-producing animals. Should not be used 30 days prior to hunting season.

Tolazoline

Synonym: Tolazine.

Molecular weight: 160.2188.

Molecular formula: C10-H12-N2 (Figure 14.6).

Chemical name: 2-benzyl-4,5-dihydro-1H-imidazole.

Tolazoline is a synthetic imidazoline derivative that functions as a nonselective α-adrenergic receptor antagonist. Tolazoline is the only FDA-approved drug for the reversal of xylazine-induced sedation in the horse, but is commonly used to reverse the effects of xylazine in cattle, camelids, and exotic species. In addition to antagonism of the α_2-receptor, tolazoline has histaminergic and cholinergic effects (Tranquilli et al., 2007) as well as direct effects on the vascular endothelium, which decreases systemic vascular resistance (vasodilation) and increasing venous capacitance (Short, 1987; Tranquilli and Thurmon, 1984). As with all the antagonists, tolazoline should be administered slowly and to effect to prevent unwanted side effects.

Tolazoline is generally thought to provide better reversal for cattle and camelid species (Hsu et al., 1987, 1989); however, there have been reports of adverse effects and fatalities in these species with appropriate and inappropriate dosing (Read et al., 2000). Tolazoline reverses the effects of detomidine in the horse better than atipamezole (Hubbell and Muir, 2006).

At doses up to five times recommended, tolazoline caused signs of gastrointestinal hypermotility, transient diarrhea, and colic (Lloyd Laboratories, 1996).

While approved for IV use, tolazoline was shown to effective when administration via the endotracheal route (Paret et al., 1999a).

The pharmacokinetics for antagonists in several species are summarized in Table 14.4.

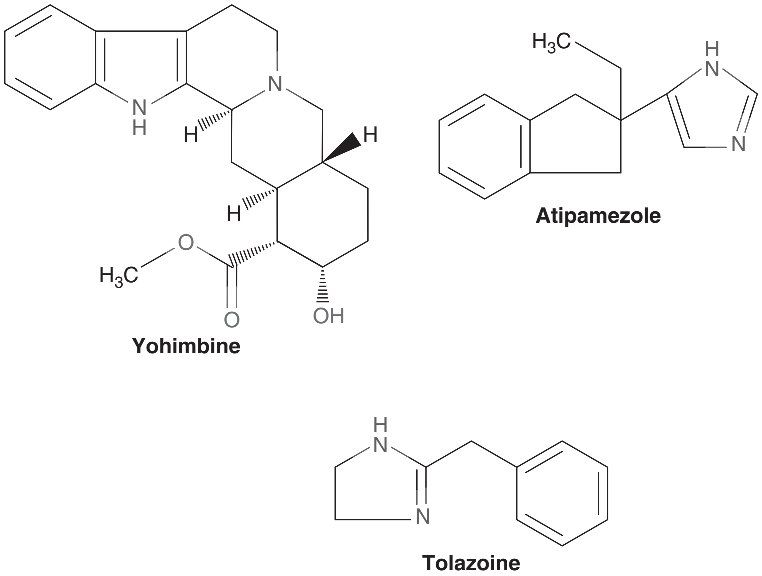

Figure 14.6 Alpha-2 antagonists.

Table 14.4 Alpha-2-adrenergic antagonists pharmacokinetics

Drug	Species	Dose	Mean residence time (minutes)	Volume of distribution (l/kg)	Clearance$_{Tot}$ (ml/kg/min)	Elimination half-life (min)	Reference
Yohimbine	Steers	0.25 mg/kg IV	86.7 ± 46.2	4.9 ± 1.4	69.6 ± 35.1	46.7 ± 24.4	(Jernigan et al., 1988)
	Horse	0.075–0.15 mg/kg IV	106 ± 72.1 to 118.7± 35.0	2.7 ± 1.0 to 4.6 ± 1.9	34.0 ± 19.4 to 39.6 ± 16.6	52.8 ± 27.8 76.1 ± 23.1	(Jernigan et al., 1988)
	Dog	0.4 mg/kg IV	163.6 ± 49.7	4.5 ± 1.8	29.6 ± 14.7	104.1 ± 32.1	(Jernigan et al., 1988)
Tolazoline	Dog	6 mg/kg via ET tube[a]		1.65 ± 0.3	10.9 ± 4.8	156 ± 81	(Paret et al., 1999b)
	Horse	4 mg/kg		1.68 ± .38	13.7 ± 3.0	160 ± 60	(Casbeer and Knych, 2013)
	Lambs	2 mg/kg IV		2.5 ± 0.7	27.1 ± 7.6[b]		(Ward et al., 1984)
Atipamezole							
	Dog						
	Cat						
	Horse						
	Dairy cow	0.2 mg/kg IV	38.3 ± 15.7	1.77 ± 0.64	48.1 ± 13.1	35.2 ± 17.9	(Ranheim et al., 1999)[c]
	Calf	0.2 mg/kg IV	48.1 ± 9.2	2.97 ± 1.4	42.9 ± 3.9	52.1 ± 7.0	(Ranheim et al., 1998)[c]
	Sheep	0.2 mg/kg IV	34.4 ± 7.9	2.0 ± 0.54	56.3 ± 9.5	34.2 ± 11.9	(Ranheim et al., 2000)[c]

[a] Following the use of xylazine and thiopental.
[b] This was in lambs 17 days of age. Clearance increased to 60 ml/kg/min by the age of 28 days.
[c] This was following medetomidine 0.04 mg/kg IV.

Representative Dosages

See Box 14.12.

Box 14.12 Tolazoline dosages

Species	Dose and route
Dogs and cats	Reversal of α_2-agonist: 4 mg/kg IV slowly
Horses	Reversal of α_2-agonist: 4 mg/kg IV slowly
Cattle	Reversal of α_2-agonist: 2–4 mg/kg IV slowly (calves 1 mg/kg IV slowly)
Llamas	Reversal of α_2-agonist: 2 mg/kg IM

Veterinary Approved Products

Tolazoline is approved by the FDA for use in the horse.

Tolazine^{TM} Injection: tolazoline HCl, 100 mg/ml (Lloyd, Inc.).

Tolazoline HCL: tolazaoline HCL, 200 mg/ml (ZooPharm).

Regulatory Information

Controlled drug status: Nonscheduled drug.

Withdrawal times: Not approved for use in horses intended for human consumption.

Pharmacodynamic Effects

Central nervous system effects: The use of α_2-adrenergic antagonists will reliably reverse the sedation, ataxia, and physiological effects caused by the α_2-adrenergic agonist in a dose-dependent manner. This is due to the blockade of the norepinephrine feedback inhibition mediated by the presynaptic α_2-adrenergic receptor activation.

All three antagonists have the potential to cause CNS excitement (agitation, fasciculations, tremors, and hyperesthesia). Yohimbine has the potential to cause seizures at higher doses via GABAergic and NMDA-mediated pathways (Dunn and Corbett, 1992). Atipamezole has only slight effects on behavior under familiar conditions, but increases neophobia (Haapalinna et al., 1997). Additionally, reversal of α_2-agonist drugs also reverses analgesia (not just sedation), which can contribute to an excited, painful recovery. It is always recommended that α_2-receptor antagonists be administered slowly and to effect to minimize these adverse effects.

Cardiovascular effects: In general, α_2-antagonists reverse or attenuate the cardiovascular changes caused by α_2-agonist drugs (e.g., xylazine) such as increased systemic vascular resistance and bradycardia. The actual cardiovascular responses are difficult to predict and are dependent on the initial agonist used, the timing of the reversal (e.g., if during the initial phase of intense peripheral vasoconstriction), the route of administration of the antagonist, and the species in question (Zeiler, 2015; Kolliasbaker et al., 1993; Savola, 1989).

Additionally, some of the α_2-antagonists are cardioprotective, both alone and when attenuating the results of α_2-agonists. Yohimbine caused an increase reperfusion of the left ventricle while also causing a reduction in left ventricular end diastolic pressure and release of lactate dehydrogenase (Sargent et al., 1994). Xylazine has been shown, using in vitro techniques, to cause coronary vasoconstriction in the dog, which was reversed by atipamezole (Teng and Muir, 2004).

Respiratory effects: Alpha-2-antagonists can reverse or attenuate the respiratory depression of α_2-agonists. At routine doses in healthy animals, α_2-agonists cause minimal changes to ventilation so antagonism of those effects do not change CO_2 or O_2 levels (Kolliasbaker et al., 1993). However, for patients with exaggerated clinical effects due to high doses, comorbidities, or coadministration of other CNS depressants, antagonism should reverse respiratory depression.

Tachypnea and hypoxemia can be seen secondary to α_2-agonist use in sheep due to activation of pulmonary intravascular macrophages (PIM) and production of acute lung injury and pulmonary edema. α_2-adrenergic antagonists attenuate the tachypnea induced by medetomidine in lambs and ewes; however, these agents failed to correct the reduction in arterial oxygen partial pressure, likely due the acute lung injury sustained (Ko and McGrath, 1995; Hsu et al., 1989; Celly et al., 1997).

Tolazoline has been used to treat pulmonary hypertension in newborns and has been shown to reduce pulmonary vascular resistance and counteract the hypoxic pulmonary vasoconstriction reflex (Paret et al., 1999b).

Muscular effects: All the α_2-adrenergic antagonists have been shown to reverse or attenuate the ataxia and muscle weakness induced by the α_2-adrenergic agonists (Hsu et al., 1989; Hubbell and Muir, 2006).

Adverse Effects/ Contraindications

Sudden death has been anecdotally reported in patients given α_2-receptor antagonists IV, presumptively from cardiovascular collapse. One possible reason for acute cardiovascular collapse could be the preservative, methylparaben, in atipamezole, which can cause histamine release and therefore reduce blood pressure. However, it is more likely that when the antagonist is given in large doses IV to patients with peripheral vasoconstriction, reflex bradycardia, and high vagal tone, the rapid relaxation of vessel tone coupled with bradycardia induces the cardiovascular collapse. Caution should be used when quickly administering an antagonist while a patient is in the acute vasoconstrictive phase. Intramuscular administration is less likely to produce acute cardiovascular changes.

CNS excitement and delirium leading to seizure activity have been reported, particularly at high doses (Ranheim et al., 2000; Read et al., 2000). Clinicians must investigate if the excitement is due to reemergence and perhaps pain or due to central CNS excitement. Many clinicians will only administer partial doses (25–50%) to minimize these effects.

The safety of α_2-adrenergic antagonists has not been established in pregnant or lactating animals, animals intended for breeding purposes, or metabolically unstable patients.

Species Differences

Cattle and small ruminants sedated with xylazine appear to have better reversal when treated with tolazoline compared with yohimbine (Hikasa et al., 1988). This is likely due to differing receptor types and binding affinities of the agonist as well as the antagonist (see Section Yohimbine).

Llamas appear to be more sensitive to the adverse effects of tolazoline compared to other species. It has been recommended to administered tolazoline at 2 mg/kg intramuscularly to minimize these adverse effects (DuBois et al., 2004; Read et al., 2000).

Tolazoline in captive bears has proven to be ineffective for the reversal of α_2-adrenergic agonists and is therefore not recommended in this group of animals (Cattet et al., 2003).

Overdose/Acute Toxicity

Tolazoline: Gastrointestinal disturbances, agitation, muscle fasciculations, tachycardia, mild hypertension, and, at high doses, ventricular arrhythmias and death were seen with the administration of tolazoline alone. Overdoses of tolazoline at five times the recommended dose have been associated with fatalities in horses (Lloyd Laboratories, 1996).

Atipamezole: Healthy dogs have tolerated up to ten times the recommended dose of atipamezole (Zoetis, 2015). No significant clinical signs were seen following a regular dose of atipamezole in nonsedated dogs (Zoetis, 2015). Signs of an overdose included excitement, panting, trembling, vomiting, mild diarrhea, and scleral injection.

Drug Interactions

Drug interaction with α_2-antagonists generally are either due to an increase in chance for hypertension (due to increase in norepinephrine) or due to exaggerated CNS stimulation (Trevor and Way, 2001). Therefore these drugs should be used cautiously with any patient that is already hypertensive or being administered drugs that might enhance heart rate or blood pressure (e.g., positive inotropes or anticholinergics). Similarly, these drugs should be given with caution with other CNS stimulants (e.g., caffeine).

Guaifenesin

History

Guaifenesin has a long history as a medical therapeutic both as a muscle relaxant as well as expectorant. It has been used as an adjunct to anesthesia in the horse since 1949 and has been used in the USA since 1965. It is still commonly used as an expectorant in people, as it is combined with dextromethorphan or used alone in many cough and cold remedies sold over the counter but, more commonly in veterinary medicine, is it administered primarily to horses for its sedation and muscle relaxation properties.

Classification

Chemistry

Synonyms: GG, glyceryl guaiacolate.

Molecular formula: C10-H14-O4 (Figure 14.7).

Molecular weight: 198.2166.

Chemical name: 3-(0-methoxy-phenoxy)-1,2-propanediol.

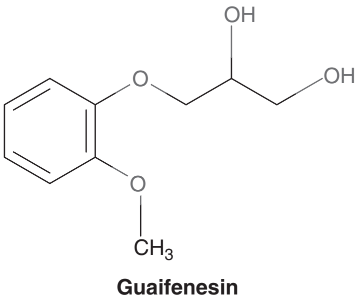

Figure 14.7 Guaifenesin.

Mechanism of Action

Guaifenesin is a central-acting skeletal muscle relaxant, but its exact mechanism of action is unknown. It selectively depresses or blocks nerve impulse transmission at the internuncial neuron level of the spinal cord, brainstem, and subcortical areas of the brain causing sedation and muscle relaxation (Muir and Hubbell, 2014; Haga et al., 2000).

Indications

In veterinary medicine guaifenesin is used as an adjunct anesthetic primarily in equine and ruminant patients, both during induction and in part of total intravenous anesthesia combinations. It is used to smooth induction and recovery as well as for decreasing the amount of induction drug needed (Brouwer, 1985). When used alone, animals may become recumbent, but surgical anesthesia is not achieved.

Physiological Effects

CNS effects: Guaifenesin is a central-acting skeletal muscle relaxant that also has CNS depressant effects. It selectively depresses or blocks nerve impulse transmission at the internuncial neuron level of the spinal cord, brainstem, and subcortical areas of the brain, causing sedation and muscle relaxation (Muir and Hubbell, 2014). Although the mechanism of action is unknown it produces CNS depression (not just muscle relaxation) based on behavior and EEG analysis (Haga et al., 2000).

Cardiovascular system: In the horse, initially there is a transient decrease in arterial blood pressure, which returns to normal, but myocardial contractile force and heart rate are relatively preserved (Hubbell et al., 1980). Many studies, in many species, have looked at the effects of guaifenesin on cardiac function when used in conjunction with other anesthetics such as ketamine, thiopental, and xylazine (Benson et al., 1985; McMurphy et al., 2002; Picavet et al., 2004). Thus, it is difficult to interpret the cardiovascular effects with respect to guaifenesin alone. However, it is likely that the additional CNS depression and muscle relaxation of guaifenesin allows for smaller doses of more-cardiovascular-depressing drugs such as thiopental or xylazine to be used. Thus guaifenesin may be useful in preserving cardiovascular function when used with other anesthetic drugs.

Respiratory: Even though guaifenesin is a skeletal muscle relaxant, in therapeutic amounts, it does not cause paralysis of the respiratory muscles (intercostal and diaphragm). Often, respiratory rate is increased but minute ventilation is unchanged (Hubbell and Muir, 2006; Muir and Hubbell, 2014; Tranquilli et al., 2007). At doses greater than needed to obtain recumbency, respiratory depression might become significant.

Muscular effects: Guaifenesin produces generalized skeletal muscle relaxation. At recommended doses, it does not affect respiratory muscles enough to significantly alter ventilation. The laryngeal and pharyngeal muscles are relaxed, which facilitates intubation of the trachea (Muir and Hubbell, 2014). At excessive doses, guaifenesin can produce a paradoxical increase in muscle rigidity (Muir and Hubbell, 2014).

Miscellaneous: Guaifenesin crosses the placenta and can be detected in the plasma of the fetus (Hubbell et al., 1980). Adverse effects of guaifenesin in newborns have not been reported.

Analgesia: Previous editions of this book have suggested that guaifenesin is analgesic, but there is little evidence to support that claim.

Pharmacokinetics

When administered to horses as a single agent, recumbency occurs in ~2 minutes and can last ~6 minutes. Sedation from a single dose may last 15–30 minutes. There is gender difference in the half-life of guaifenesin in ponies: males have a $T_{1/2}$ of ~85 minutes whereas in the female $T_{1/2}$ is ~60 minutes (Davis and Wolff, 1970).

Metabolism

Guaifenesin undergoes biotransformation in the liver to a glucuronide, which is then excreted in the urine (Davis and Wolff, 1970).

Adverse Effects/ Contraindications

The manufacturer cautions against administration with physostigmine, but does not explain the interaction. The use of guaifenesin in cows at concentrations exceeding 5% has been associated with red blood cell hemolysis (Wall and Muir, 1990).

Dose

Guaifenesin has a moderately high therapeutic index as three to four times the dose required to produce recumbency of the horse can be administered before death occurs (Funk, 1973). The primary disadvantage in the use of guaifenesin is the large volume of solution required to produce relaxation.

For horses the dose indicated on the label is 110 mg/kg IV. For preanesthetic sedation (prior to administration of other IV anesthetics) the dose is 75–110 mg/kg IV (lower doses used when used in combination with other CNS depressants such as thiopental or ketamine). For cattle the dose is 50–100 mg/kg IV.

Species Differences

Horse: Horses are still routinely sedated and anesthetized using guaifenesin. Generally, it is combined with or given immediately prior to other anesthetic drugs, such as xylazine, ketamine, or thiopental (see Section Triple Drip). Guaifenesin aids in producing a smooth induction and recovery as well as minimizing the amount of other drug needed to produce the desired effect. The administration of xylazine (1.1 mg/kg) prior to guaifenesin reduces the IV dose necessary to induce lateral recumbency in adult horses (Hubbell et al., 1980). When using guaifenesin for sedation immediately prior to induction with ketamine or thiopental, it should be administered until the horse begins to knuckle the fore or hind limbs. At that point, the guaifenesin should be discontinued and the induction agent immediately given. Hemolysis of red blood cells (as seen in cattle) has not been associated with guaifenesin concentrations up to 10% in horses (Grandy and McDonell, 1980).

Cattle: The use of guaifenesin in cattle and small ruminants is similar to that of horses. The use of guaifenesin in concentrations exceeding 5% has been associated with a dose-dependent red blood cell hemolysis (Wall and Muir, 1990).

Dogs: Guaifenesin had been used to treat strychnine poisoning in dogs (Bailey and Szabuniewicz, 1975), but is rarely used for sedation or anesthesia of dogs.

Triple Drip

Guaifenesin has been extensively used in combination with ketamine and xylazine. In horses, the mixture is commonly comprised of guaifenesin (50 mg/ml), ketamine (0.5–2 mg/ml), and xylazine (0.5–1.0 mg/ml). In cattle and small ruminants, guaifenesin (50 mg/ml) has been combined with ketamine (1–2 mg/ml) and xylazine (0.05–0.1 mg/ml). These combinations can be administered as induction agents, but are more routinely administered following anesthesia induction for maintenance of anesthesia. They should be administered to effect, but generally are administered ~1–2 ml/kg/h (Tranquilli et al., 2007). Guaifenesin has similarly been combined with detomidine (40 μg/ml) and ketamine (4 mg/ml), and administered at a continuous infusion rate of 0.8 ml/kg/min (Taylor et al., 1998).

Guaifenesin (50 mg/ml) can also been mixed with thiopental (2 mg/ml), and similarly used for maintenance of anesthesia at ~1.5 ml/kg/h (Muir and Hubbell, 2014).

Drug Interactions

Guaifenesin is often mixed with ketamine and xylazine ("triple drip") and with barbiturates with apparent stability. The manufacturer cautions against administration with physostigmine, but does not explain the interaction.

Overdosage/ Acute Toxicity

Guaifenesin has a wide therapeutic margin. Overdose can be associated with respiratory depression and muscle rigidity. Elimination in horses is rapid. Therefore, an overdose can be managed with supportive care until plasma levels decrease.

The use of guaifenesin in cows at concentrations exceeding 5% has been associated with red blood cell hemolysis (Wall and Muir, 1990).

Regulatory Information

Guaifenesin is FDA approved as a skeletal muscle relaxant for use in horses, but not for use in meat-production animals. Guaifenesin is approved for use in people as an expectorant and included in over-the-counter medications alone, or combined with dextromethorphan in cough and cold remedies.

Controlled drug status: Guaifenesin is not a scheduled controlled drug.

Withdrawal time: Guaifenesin is not approved for food-producing animals.

Extra-label use in food animals: 3 days for meat and 48 hours for milk.

Veterinary Products

Guailaxin: sterile powder 50 g (Fort Dodge Animal Health).

Gecolate/Glycodex Injection: 5% solution (50 mg/ml) (Summit Hill Laboratories).

How Supplied

Guaifenesin is supplied as a 5% (50 mg/ml) solution or as a white powder that is reconstituted to a 5% solution with water or 5% dextrose solution. It is not readily water soluble and easily precipitates out of solution at 22°C (72°F) or cooler (Funk, 1973). Warming and agitation usually eliminate the precipitate.

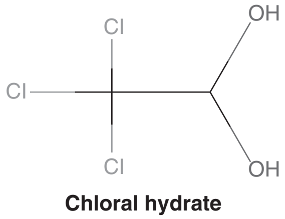

Figure 14.8 Chloral hydrate.

Chloral Hydrate

History

Chloral hydrate is the ingredient in the notorious “Mickey Finn,” named after a Chicago bartender who used the sedative properties combined with alcohol to rob his victims. It was introduced into medicine as a hypnotic in 1869 (Gauillard et al., 2001) and was among the first CNS depressants to be used in veterinary medicine. Chloral hydrate is rarely used to treat insomnia in people and for sedation in children, but is no longer used in conjunction with human anesthesia. It is a mutagen and a potential carcinogen and is rarely if ever used in veterinary medicine. This drug is discussed in greater detail in the seventh edition of this textbook.

Classification

Chemistry

Molecular formula: C2-H3-Cl3-O2 (Figure 14.8).

Molecular weight: 165.403.

Chemical name: 1,1,1-Trichloro-2,2-dihydroxyethane.

Chloral hydrate is the end product of chlorination of acetic aldehyde and addition of water. Chloral hydrate volatilizes on exposure to air and has an aromatic, penetrating odor. One gram of chloral hydrate is soluble in 0.25 ml water and in 1–2 ml of fat solvents.

Mechanism of Action

The mechanism of action of chloral hydrate is unknown, but it has been hypothesized to be a GABA agonist based on its synergy of action with other GABA agonists (ethanol, benzodiazepines) and the fact that the benzodiazepine antagonist, flumazenil, has been successfully used to treat chloral hydrate overdose in people (Gauillard et al., 2001).

Indications

Chloral hydrate has been used for general sedation and as an adjunct to anesthesia primarily in horses and cattle. It is rarely used in modern veterinary practice.

Physiological Effects

Chloral hydrate is a sedative hypnotic drug. It produces a dose-dependent sedation with a wide margin of safety when used at sedative doses, and was historically used as a sleep adjunct in people. It is, however, a poor anesthetic and when administered at anesthetic doses, the margin of safety is narrow. At anesthetic doses (compared with sedative doses), chloral hydrate produces significant respiratory and cardiovascular depression. Although chloral hydrate produces CNS depression, it does not provide analgesia and muscle relaxation is poor.

When administered IV, the sedative effects are seen almost immediately. Following oral administration, sedation occurs in 30–60 minutes. Choral hydrate is metabolized by alcohol dehydrogenase into trichloroethanol (TCE) and trichloroacetic acid. TCE is an active metabolite (Gauillard et al., 2001). The half-life of chloral hydrate is short (minutes), but the half-life of TCE is greater than 8 hours in humans (Gauillard et al., 2001).

The effects of chloral hydrate can be intensified when administered with other CNS depressants. Interestingly, chloral hydrate slows ethanol metabolism, thereby enhancing the effects of ethanol.

Chloral hydrate is irritating to the esophagus and GI tract when administered orally and should be administered in a diluted solution or following a meal. When administered intravenously, chloral hydrate can cause tissue necrosis and sloughing when administered perivascularly. When administered intraperitoneally, pain, ileus, and fibrosis may occur.

Dose

Cattle: The dose used for sedation is 0.025–0.05 ml/kg IV. To produce general anesthesia, the dose is 0.1–0.25 ml/kg IV until the desired effect is produced. Cattle usually require a lower dosage on the basis of body weight compared with horses. Oral administration is not recommended due to GI irritation.

Horses: The dose for sedation is 0.025–0.05 ml/kg IV. To produce general anesthesia, the dose is 0.1–0.25 ml/kg IV until the desired effect is produced. Oral administration is not recommended due to GI irritation.

Regulatory Information

Chloropent (chloral hydrate, magnesium, and pentobarbital) is approved for use in cattle and horses.

Controlled drug status: Chloral hydrate is Schedule IV controlled drug.

Withdrawal times: Chloropent (chloral hydrate, magnesium, and pentobarbital) is approved for use in dairy and beef cattle. FARAD lists a zero meat withdrawal time, but no recommendations for milk following sedation with chloropent.

Not intended for use in horses intended for human consumption.

Veterinary Products

Chloropent: Zoetis, approved for use in horse and cattle.

How Supplied

Presently, chloral hydrate is approved only for use in combination with pentobarbital and magnesium sulfate (chloropent) for anesthesia of cattle and horses. Each ml contains 42.5 mg of chloral hydrate, 8.86 mg of pentobarbital, and 21.2 mg of magnesium sulfate in 33.8% propylene glycol and 14.25% ethyl alcohol.

The addition of magnesium (mixture of 12% chloral hydrate and 6% magnesium sulfate) to a chloral hydrate solution increases the muscle relaxation and duration of action of chloral hydrate. The combination of chloral hydrate, magnesium sulfate, and pentobarbital sodium (previously marketed as Chloropent and Equithesin) provides some of the desirable depressant actions of each compound but minimizes the adverse effects of each by using smaller doses of each individual drug.

Local Anesthetics

Thomas W. Vickroy

Introduction

Agents that are classified as local anesthetics act reversibly to prevent transmission of electrical impulses in nerve fibers and other excitable tissues. In most common applications, local anesthetics are administered to animals with the intent to exert actions that are restricted to regions of the body proximal to the site(s) of drug administration. However, as discussed elsewhere in this text, some agents are administered in different ways with the intent to produce broader systemic actions and, in that context, their actions are not classified as local anesthesia. The most widely accepted mechanism by which these drugs are thought to act involves direct binding to, and reversible blockade of, voltage-gated sodium ion (Na^+) channels in cell membranes. This singular action prevents Na^+ ion entry into nerve cells during periods of intense membrane depolarization, which prevents transmission of nerve impulses. The primary consequence of local anesthetic action is a reversible graded attenuation of sensation to pain and other sensory stimuli within affected body regions. The ability of local anesthetics to produce a selective decrease in pain sensitivity is noteworthy insofar as those effects occur without significant alteration in an animal's level of consciousness nor any substantial depression of central nervous system (CNS) functions. This combination of desirable properties, including reversibility, anatomically restricted effects, and selective sparing of other neuronal functions, has helped foster the widespread acceptance and use of these agents in both veterinary and human medicine.

Throughout the modern history of drug discovery and development, it has been common for the initial lead compound within many drug classes to be identified and isolated from a natural source, and that is certainly the case for the local anesthetics. For many centuries, native peoples living in the Andes mountains of South America chewed extracts of the leaves from the coca shrub (*Erythroxylon coca*) for both stimulatory effects and euphoric properties. However, it was not until 19th century that the chemist, Albert Niemann, reported the chemical synthesis of cocaine, the principal active ingredient in coca plant extracts. The local anesthetic properties of this plant alkaloid became known in Western medicine soon thereafter when Niemann reportedly discovered that this newly isolated compound caused numbness in his tongue when he tasted the synthetic cocaine. The ready availability of synthetic cocaine led to studies by Sigmund Freud into the drug's physiological actions and its eventual introduction into clinical usage for surface analgesia in ophthalmology and eventually for parenteral use to block nerve conduction. As described later in Section Amino-Ester versus Amino-Amide Classes, cocaine is considered to be the archetype for the amino-ester class of local anesthetics and its discovery led to the synthesis and introduction of other amino-ester local anesthetics into clinical use, including benzocaine (1900), procaine (1904), dibucaine (1929), tetracaine (1930), proparacaine (1953), and others. The other broad chemical class of local anesthetics, which are known commonly as amino-amide agents, was brought into clinical use with the introduction of lidocaine in 1948, followed by mepivacaine (1957), prilocaine (1960), bupivacaine (1963), and other agents. The significance of the amino-amide versus amino-ester classifications of local anesthetics is discussed in Section Amino-Ester versus Amino-Amide Classes.

Clinical Uses in Veterinary Medicine

In the clinical setting, most actions of local anesthetics are readily reversible and devoid of any significant effect on an animal's consciousness or other functions that are associated with the CNS. This combination of properties makes these agents very useful for preventing pain that would normally occur during a wide variety of treatments and procedures. Disruption of neural transmission in sensory afferents with a local anesthetic agent can be accomplished in several distinct ways,

Companion Website: www.wiley.com/go/riviere/pharmacology

including local tissue infiltration, splash blocks, intravenous regional nerve blocks, digital nerve blocks, or by administration of local anesthetics in close proximity to spinal nerve tracts (epidural and intrathecal administration) in order to disrupt pain transmission into higher CNS centers. When these agents are administered correctly with particular attention to anatomical injection site, injection volume, dose, and coadministration of a vasoconstrictor agent, it is possible to produce complete analgesia in a targeted region of the body. In addition, local anesthetics may contribute further to pain management in patients by interfering with the central facilitation (wind up) and sensitization of nociceptive pathways.

Local anesthetic agents are used clinically in many different ways for local or regional blockade of pain in both small and large animal species. The following listing includes some of the more common applications for local anesthetic use, although some specialized applications are not included here.

Topical anesthesia: In order to be effective for topical anesthesia, the local anesthetic agent must be capable of penetrating through open wounds, skin, or mucous membranes. Penetration of mucous membranes is significant for many local anesthetics and can give rise to significant system absorption, most notably from the respiratory tract. The capacity of most local anesthetics to penetrate intact skin is markedly limited, but certain formulations can be effective for producing superficial dermal anesthesia.

Infiltration anesthesia: These applications require that a high concentration of agent is injected directly into tissue without particular concern for the anatomical location of nerve tracts in the vicinity of the injection site. In view of the requirement for administering a relatively high amount of drug for infiltration anesthesia, there is a greater risk of systemic absorption and toxicity. Such risks are mitigated commonly by inclusion of a vasoconstrictor agent such as epinephrine along with the local anesthetic.

Splash blocks: This clinical use refers to direct application of a local anesthetic to a site of interest, such as proximal to the body wall in association with abdominal surgery or adjacent to ovarian ligaments following ovariohysterectomy. Splash blocks are also used in association with oral surgical procedures, including application into tooth extraction sites. Such diffuse applications of local anesthetics have been shown to reduce general anesthetic requirements in some clinical procedures and are therefore considered beneficial.

Field-block anesthesia: This application commonly involves injection of a local anesthetic immediately adjacent and perpendicular to sensory nerves that innervate a particular region of the body. When performed correctly, local anesthetics used in this manner can effectively ablate all sensations distal to the line of injection sites. In a clinical setting, this particular application requires a detailed knowledge and accurate placement of drug immediately adjacent to sensory nerve tracts that innervate the body region. Nerve block anesthesia represents a more confined application in which the local anesthetic is injected in immediate proximity to a nerve or nerve plexus. The risk of toxicity is considerably less in this application due to more restricted drug placement and the use of limited quantities.

Intravenous regional nerve block (IVRA or Bier block): These clinical applications provide a rapid and reliable method for evoking short-term anesthesia and muscle relaxation of an animal's distal extremities. The blood supply to a distal limb is isolated by a tourniquet and the local anesthetic is injected intravenously distal to the tourniquet. The mechanism(s) by which local anesthetics produce IVRA is unknown but may arise from local diffusion of the agent into tissue and action on nerve endings and nerve trunks. Problems associated with this method include systemic toxicity if the tourniquet leaks or is released before the local anesthetic has become bound to tissue. Harmful effects secondary to prolonged disruption of the blood supply with the tourniquet also present some concern with these applications.

Soaker-type catheter: In this approach, which is commonly referred to as a diffusion or wound catheter, a length of sterile fenestrated tubing is placed surgically at a painful site for the continuous or intermittent administration of local anesthetics. Soaker-type catheters are used in association with limb amputation or large tumor resection or a course of palliative care.

Spinal and epidural anesthesia: With spinal (subarachnoid) anesthesia, local anesthetic is injected into the lumbar-dura space immediately surrounding the spinal cord where it mixes with the cerebrospinal fluid (CSF). Besides producing the block of sensory innervation, the most notable physiological effect is the sympathetic blockade produced in spinal nerve roots. The degree of spinal anesthesia produced by this method is dependent on the injected volume as well as the drug concentration and the extent of drug diffusion along the spinal cord. Since preganglionic sympathetic fibers are very sensitive to local anesthetic blockade, the sympathetic block typically extends in a rostral direction for one or two additional segments. The movement of anesthetics along the neural axis is determined by volume of injection and by patient position. In epidural anesthesia, drug is injected into the space between the ligamentum flavum and the dura mater that covers the spinal cord. The presumptive site of drug action is spinal nerve roots, although some drug is likely to be absorbed into the epidural space where additional effects could take place.

Mechanisms for Local Anesthetic Action

Multiple lines of evidence indicate that the primary cellular target for local anesthetic action is (are) one or more specific binding sites located within ion-specific channels in the plasma membranes of nerves and other excitable cells (see review by Nau and Wang, 2004). When drug binding sites are occupied by a local anesthetic, the channels are unable to conduct Na^+ ions inwardly as normally occurs during periods of intense membrane depolarization. As a consequence of this blockade, the threshold for electrical excitation of the nerve membrane increases, while the rate of rise of the action potential, the speed of impulse conduction, and the safety factor for impulse conduction are collectively reduced. Eventually, as fractional drug occupancy of channel binding sites approaches saturation, the affected regions of nerve cells become incapable of generating or conducting action potentials thereby causing failure of nerve impulse conduction. Results from experimental studies indicate that the locations of local anesthetic binding sites are deep within the Na^+ channel complex and appear to be at or near the axoplasmic (inner) surface of the membrane (Butterworth and Strichartz, 1990). This conclusion is based in part on early experimental observations that quaternary analogs of local anesthetics, which are highly charged at physiological pH, selectively block nerve impulse conduction when applied internally to isolated nerve axons, but are relatively ineffective when applied externally. In keeping with this model, it would seem essential that local anesthetic agents must first permeate the nerve membrane in order to access specific binding sites within Na^+ channels. This and other observations have led to the hypothesis that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the membrane (Narahashi and Frazier, 1971). It is well-established that voltage-gated Na^+ channels in mammalian neurons are comprised of glycosylated proteins with an aggregate molecular size in excess of 300,000 daltons. The largest of the protein subunits that form the channel complex contains four homologous domains, each containing six alpha-helical transmembrane segments (Figure 15.1). This component of the channel complex is considered to contain the specific binding pocket for local anesthetic agents (Yu et al., 2005). Although several alternative models have been proposed to explain the mechanism for local anesthetic action, including a variety of physicochemical models (Courtney and Strichartz, 1987), none of these hypothetical models are as widely accepted as the Na^+ channel binding site model described above.

Activity-Dependent Blockade

The extent or degree of conduction block that occurs in the presence of a given concentration of local anesthetic depends on several factors, including the resting membrane potential, the degree of nerve stimulation (firing activity), the length of axon in which Na^+ channels are blocked, and the duration of exposure to drug. Local anesthetics display an enhanced capacity to block nerve impulse conduction in nerves that are depolarized and actively firing (frequency-dependent blockade), presumably due to an increased capacity for drug to enter channels that are in the open state (ion conducting) versus an inactivated or nonconducting closed state. Once bound to a channel, a local anesthetic stabilizes Na^+ channels in an inactivated state that is incapable of conducting Na^+ ions (Butterworth and Strichartz, 1990; Courtney and Strichartz, 1987). Some but not all local anesthetic agents exhibit differences in the extent of frequency-dependent nerve blockade owing to differences in the rates of drug dissociation from the channel binding site. For agents that dissociate more rapidly from channel binding sites (small hydrophobic agents), effective channel blockade requires more rapid firing activity in order that the rate of drug binding during the action potential exceeds the rate of drug dissociation from Na^+ channels between action potentials. From a clinical perspective, the impact of this frequency-dependent blockade has limited relevance for sodium channel blockade in sensory nerves, but is considered to be important for Na^+ channel blockade in myocardial tissues, where the antiarrhythmic actions of these agents can be impacted significantly by the relative rates of drug association and dissociation from channel binding sites.

Differential Effects on Nerve Fibers

By virtue of the pervasive presence of voltage-gated Na^+ channels in nearly all nerve cells, it seems likely that local anesthetics would have the capacity to block impulse conduction in most if not all neurons that undergo sodium-dependent firing. Nevertheless, numerous reports from studies in isolated tissues and intact living animals have provided solid evidence for the ability of local anesthetics to exert differential or selective blocking actions on nerve fibers that transmit impulses associated with different sensory modalities or functions. In general, these studies indicate that local anesthetics first cause diminished sensation to pain and temperature along with loss of other sensory modalities

Figure 15.1 Theoretical model for sodium channel blockade by local anesthetics. The four homologous transmembrane domains (DI, DII, DIII, and DIV) that form the pore of the Na^+ channel are depicted as an array of squares from the perspective of looking at the outer membrane surface. Membrane depolarization causes conformational shifting of voltage-sensing domains and opening of the channel pore (step 1). As sodium ions enter through the open channel, membrane potential (E_{MEM}) becomes positive leading to inactivation of the open channel (step 2). Ultimately, the channel returns to a closed state (step 3) and the cycle repeats. Local anesthetics bind to sites on domains III and IV near the inner membrane surface when channels are in an open or inactivated state (step 4). Once occupied by local anesthetic, the channel becomes incapable of conducting Na^+ ions.

(touch and deep pressure), followed by diminished proprioception and motor function. In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated A fibers (mediating pain and temperature sensations) are blocked preferentially before larger myelinated fibers that mediate postural, touch, pressure, and motor information. The underlying mechanism(s) that give rise to this differential blockade are incompletely understood, but several factors may contribute, including fiber diameter and extent of axonal myelination. However, the early hypothesis that sensitivity to local anesthetic blockade was inversely correlated to nerve fiber diameter does not fit with all experimental observations (Fink and Cairns, 1984; Franz and Perry, 1974; Huang et al., 1997) and thus it appears unlikely that fiber size per se determines susceptibility to local anesthetic block under steady-state conditions. The spacing between nodes of Ranvier could also contribute to differential sensitivity to local anesthetic action since internodal spacing typically increases in proportion to the diameter of nerve fibers. Because a fixed number of nodes must be blocked in order to prevent impulse conduction, small fibers with closely spaced nodes of Ranvier may be blocked more readily following exposure to local anesthetics. Finally, differences in tissue barriers and the relative locations of smaller C fibers and A fibers within sensory nerve trunks may also contribute to the apparent differences in nerve sensitivities to local anesthetic action. It is important to note that substantial controversy still surrounds the basic premise for differential susceptibility of nerve fibers to local anesthetic action. Since the primary clinical goal of local anesthesia is to alleviate or prevent pain, it would be beneficial if motor functions were spared completely when sensory modalities are attenuated or, at a minimum, that any effect of local anesthetics on motor function and

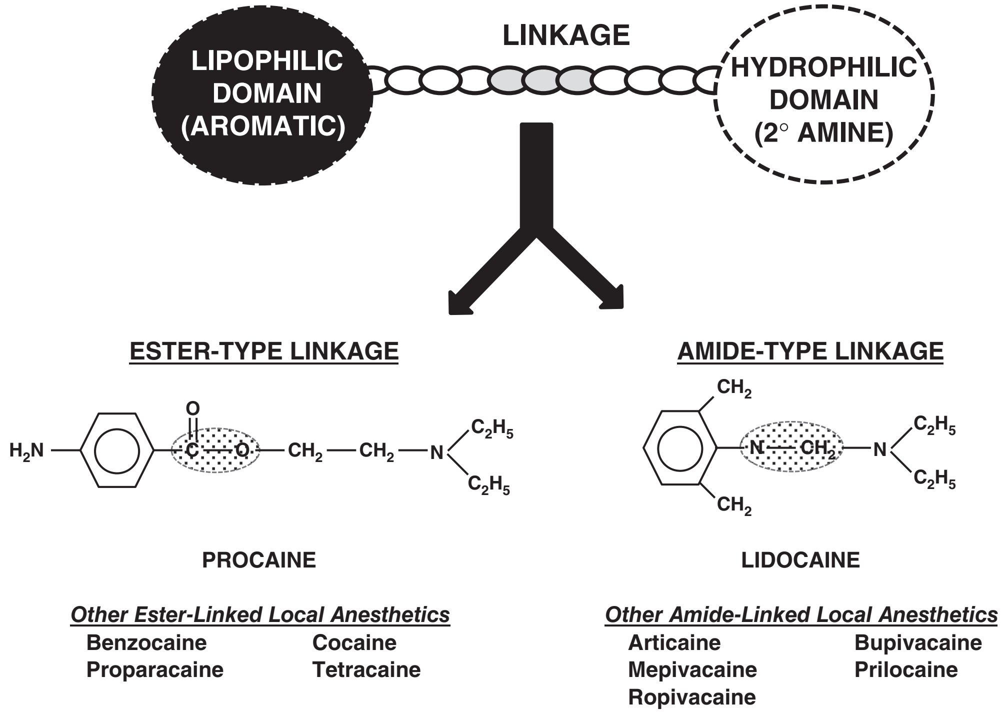

Figure 15.2 Representation of the core structural elements for two major classes of local anesthetic agents. Chemical structures for archetype representatives of the ester-linked agents (procaine) and amide-linked agents (lidocaine) are shown with the carboxylic acid ester and amide chemical bonds, respectively, highlighted within the shaded region.

proprioception would dissipate completely before sensory functions were recovered fully. Unfortunately, this is not always the outcome in clinical practice. A practical and important example in veterinary medicine occurs in horses, where limb nerve blocks are performed to assist with certain clinical procedures or diagnostic tests. In such instances, impaired proprioception increases the risk of injury if the horse is permitted to move about without proper restraint. Such heightened risk of injury is one reason why many racing authorities have banned the use of local anesthetics in horses prior to racing. The long-acting local anesthetic etidocaine was withdrawn from the market owing to problems associated with persistent motor deficits in horses and some other species.

Chemical Properties

Amino-Ester versus Amino-Amide Classes

Local anesthetics are organic bases, but are classified as amphipathic substances since nearly all agents contain both lipophilic (aromatic) and hydrophilic (substituted amine) moieties. These chemically diverse regions of the molecule are linked by an intermediate-length carbon chain that contains either an amide bond or ester bond, which gives rise to the frequent subclassification of local anesthetics into amino-amide and amino-ester classes of agents (Figure 15.2). The distinction between amino-amide and amino-ester local anesthetic agents represents far more than some arcane chemical classification insofar as enzyme-catalyzed disruption of these bonds within the linker regions renders agents incapable of producing a local anesthetic effect and, in many cases, represents a significant route for inactivation. In general, ester-linked agents are highly susceptible to enzyme-catalyzed hydrolysis of the ester bond by different families of esterase enzymes and, as a consequence, tend to have much shorter durations of action as compared with amide-linked agents. This is an important consideration in animals that have a diminished overall level of esterase enzyme activities secondary to disease processes, genetic abnormalities, or, perhaps most importantly, prior exposure to agents that cause reversible or irreversible inhibition of esterase enzymes. By comparison, the amino-amide link is more resistant to enzymatic degradation and is highly stable under temperature extremes, including heat sterilization.

Effect of Local pH

The physical chemical properties and structure–activity relationships for local anesthetic agents have been reviewed in detail previously (Courtney and Strichartz, 1987). Most local anesthetics contain a tertiary amine as the hydrophilic group and an unsaturated aromatic ring as the lipophilic group. In general, tertiary amines are poorly soluble in water and, accordingly, many local anesthetics are prepared as hydrochloride salts in order to improve water solubility and facilitate their formulation as injectable aqueous solutions. Since local anesthetics are weak organic bases (B), with typical pK_a values ranging from 8 to 9, the hydrochloride salts form mildly acidic solutions in water, which tends to enhance the chemical stability of catecholamines, such as epinephrine, that are sometimes included for their vasoconstrictor action. Under usual conditions of administration, it is likely that the pH of the local anesthetic solution rapidly equilibrates with that of the extracellular fluid environment. Experimental studies support a model (Figure 15.3) wherein the unprotonated species of the local anesthetic (B^0) is the predominant form that is able to diffuse across cellular membranes, whereas the less permeable cationic species (BH^+) is the predominant form that interacts preferentially with Na^+ channels. In consideration of this model, wherein the unprotonated form of drug provides improved access to the target site and the protonated form has greater affinity for blocking Na^+ channels, it is evident that pH of extracellular fluid can influence the actions of local anesthetics. The relative concentrations of uncharged (B^0) and cationic forms (BH^+) of drug at equilibrium are related to the pKa of the ionizable group as well as the local pH and can be estimated mathematically by the Henderson–Hasselbalch relationship as follows:

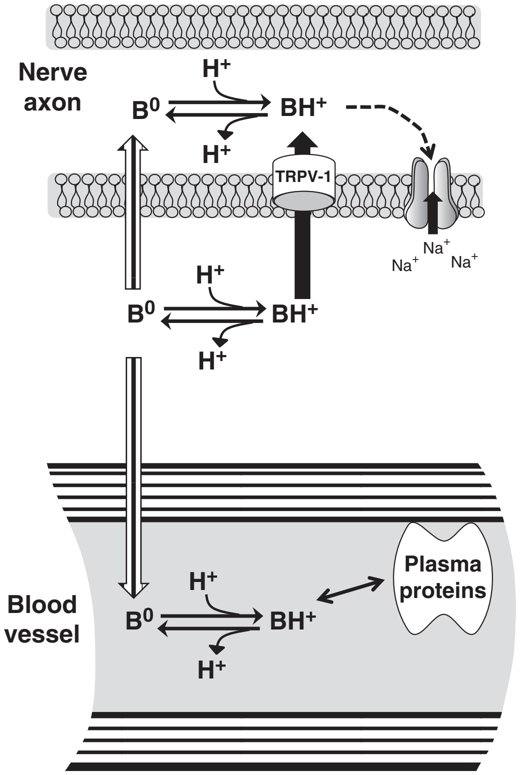

Figure 15.3 Principal routes for local anesthetic movement following subcutaneous injection. Passive diffusion (thick striped arrows) is likely to be the primary process by which the unprotonated (B^0) forms of local anesthetics enter either nerve axons or blood vessels. In addition, the cationic form (BH^+) may enter neurons via transient receptor potential vanilloid subtype-1 channels (TRPV-1), if present, and allow for blockade of sodium channels from the axoplasmic side.

$$pH = pK_a + \log \frac{[B^0]}{[BH^+]} \tag{15.1}$$

When solution pH is equivalent to the pKa of a local anesthetic, the relative concentrations of $[B^0]$ and $[BH^+]$ are equal. However, in situations where the extracellular fluid becomes mildly acidified (reduced pH), such as in association with localized tissue inflammatory reactions, the relative ratio of $[B^0]/[BH^+]$ decreases in accordance with the above relationship and the cationic form becomes the predominant species. A modest shift in the pH of extracellular fluid can cause a significant shift in the equilibrium between cationic and neutral forms and thereby affect the rate at which drug is able to diffuse through the nerve cell membrane and reach the target binding site. Another situation where the equilibrium concentrations of charged species could be important is with regard to local anesthetic diffusion across the maternal–fetal barrier in the placenta, where fetal blood is slightly acidic (lower pH) relative to maternal blood. However, it is important to recognize that the impact from shifts in the acid–base equilibrium can be influenced by other factors for certain agents, including differences in drug–protein binding, differences in the membrane permeability of neutral and cationic species, as well as differences in the Na^+ channel blocking activity for the neutral and cationic species. For example, it has been reported that the unprotonated (B^0) form of some local anesthetics can exhibit significant channel-blocking activity, whereas the uncharged form of other agents are nearly devoid of activity. In addition, the capacity for the charged cationic form of local anesthetics to gain access to the cytoplasmic surface of the nerve cell membrane by passage appears to not be limited by transmembrane diffusion of the unprotonated neutral form as commonly proposed. For example, research studies have demonstrated that a permanently charged derivative of lidocaine has the ability to permeate neuronal membranes by passage through a family of nonselective cation channels known as transient receptor potential vanilloid subtype 1 or TRPV1 channels (Binshtok et al., 2009). These and related membrane channels are expressed primarily within sensory neurons and, when activated by membrane depolarization, permit influx of inorganic cations, primarily Ca^{2+} and Na^{+}.

However, in light of the selective expression of TRPV1 channels in a subset of sensory neurons, this alternate pathway for local anesthetic entry and blockade of axonal Na^{+} channels (Figure 15.3) raises the potential to achieve greater pharmacological selectivity and thereby avoid unwanted effects on motor nerves and possibly other nonnociceptive modalities (Blumberg, 2007). In addition to being the responsive element for changes in molecular charge under different conditions of pH, the hydrophilic moiety is considered crucial for influencing drug binding affinity to target sites within Na^{+} channels. Structure–activity studies indicate that the intermediate linking chain is likely to be important for proper alignment of the lipophilic and hydrophilic ends of the drug, with a length of three to seven carbon atoms being optimal for channel blocking activity. In general, detailed studies of the structure–activity relationship for local anesthetics have revealed that: (i) highly lipophilic agents exhibit higher potencies, which may reflect an increased binding affinity for target sites as well as enhanced partitioning into the membrane microenvironment; (ii) highly lipophilic agents exhibit longer durations of action possibly due to enhanced distribution into nerve cell membranes plus reduced accessibility to degradative enzymes in plasma and liver; (iii) higher lipophilicity is associated with a greater propensity for toxicity and a smaller therapeutic index; and (iv) agents that are smaller in size exhibit faster rates for dissociation from target receptor sites and, accordingly, display a greater extent of frequency- and voltage-dependent actions in rapidly firing neurons.

Stereoisomerism

Several of the local anesthetic agents that are used clinically, notably those that contain a pipcolyl xylidine (PPX) group within the hydrophilic region, can exist as pairs of optical stereoisomers. As readers may recall from general chemistry, stereoisomers are compounds that have identical chemical structures but differ in the three-dimensional spatial arrangement of constituent groups around a particular atom (usually a carbon atom), which represents the chiral center. The different spatial orientations of stereoisomers for local anesthetics form non-superimposable mirror images of one another that are known as enantiomers. A useful analogy for visualizing differences between chemical enantiomers is to consider enantiomer pairs to be similar to a person's right and left hands. When the right and left hands are oriented with the palms facing in the same direction, they are not superimposable even though they contain the same array of fingers (constituent groups). Enantiomers are most commonly designated as R(+) or *dextro* and S(-) or *levo* and, in the case of local anesthetics, certain enantiomers are known to produce pharmacological actions that are both quantitatively and qualitatively different. More specifically, the S(-) enantiomers of several local anesthetics have been reported to produce fewer adverse effects in the central nervous system (CNS) and the cardiovascular system (CVS) as compared to the R(+) enantiomers of the same drugs. In support of these observations, enantiopure preparations of S(-) isomers have been found to exhibit improved safety profiles relative to the racemic (50 : 50) mixture of enantiomers that are formed during routine chemical syntheses. Accordingly, enantiopure preparations of the S(-) stereoisomer of the local anesthetic bupivacaine have been developed and marketed, as described in Section Levobupivacaine.

Stability and Formulations

Local anesthetics that are used clinically are chemically quite stable substances with aqueous solutions being remarkably stable at ambient temperatures (15–30°C). In the case of lidocaine, aqueous solutions are known to withstand autoclave sterilization (15 PSI at 121°C for 15 minutes), although it should be noted that some local anesthetic formulations contain the catecholamine epinephrine, which readily undergoes spontaneous oxidation under extreme conditions. Such formulations should be protected from elevated temperatures as well as direct sunlight in order to preserve added catecholamine. Formulations that include epinephrine are packaged and sold in amber-colored containers to afford protection against photochemical degradation, but still have a reduced shelf life compared to formulations without epinephrine. Like any other injectable drug solution, solutions of local anesthetics that become cloudy, discolored, or contain visible precipitates should be discarded.

Local anesthetics are available in a wide array of formulations, a fact that underscores the need for careful attention to product labels. Lidocaine, the most widely used local anesthetic in veterinary practice, is available as sterile injectable solutions for parenteral use, gels and ointments for topical use, aerosol sprays for airway application, and patches for transdermal application. Multi-dose injectable formulations routinely contain preservatives that have been linked to adverse actions, including sodium metabisulphite (neurotoxicity), methylparaben (hypersensitivity reactions), benzyl alcohol (intoxication in felines), and EDTA (transient tetany). Preservative-free preparations are available and essential for intrathecal injection owing to the high potential for nerve damage by preservatives. On a related matter, it is interesting to note that the specific gravity (density) of local anesthetic formulations can be a critical factor in spinal anesthesia. In order to restrict the movement of drug solution within the subarachnoid space, anesthesiologists use solutions of local anesthetics that are rendered hyperbaric (specific gravity ≫1) by the addition of a high concentration of glucose. Human formulations of hyperbaric solutions are currently available, although use of these agents is typically limited in veterinary practice. There is little evidence for acute allergic reactions to local anesthetics in humans or nonhuman species and therefore this poses little concern.

General Pharmacological Considerations

In addition to their shared mechanism of action and core chemical structures, most local anesthetics exhibit an overlapping set of pharmacological actions, including similarities in their pharmacodynamic actions and pharmacokinetic properties. While differences or unique properties of selected individual agents are summarized later in this chapter, it is important to consider properties that are shared among many of the local anesthetics that are used routinely in clinical practice.

Onset and Duration of Action

The amount or dose of local anesthetic that is required to block sensory transmission is highly dependent on the free (unbound) concentration of drug in the cationic form that is available at the channel binding site. Higher lipid solubility translates into greater potency or lower effective dose but, unfortunately, also correlates with organ system toxicity, especially within the cardiovascular and central nervous systems. For this reason, the more potent local anesthetic agents tend to have reduced margins of safety. Since these agents are administered at relatively high concentrations and, in most situations, are used to produce local actions, the relative potencies of local anesthetics are generally considered to be of lesser importance than may be the case for other types of agents that exert systemic actions at sites far removed from the administration site. The time delay between administration of a local anesthetic and the resultant sensory block is influenced by many factors, including proximity of drug placement relative to target sensory nerves, the concentration of drug, and certain physical–chemical properties of the drug, including molecular weight (size) and the relative fraction of drug in the charged/neutral form. Predictably, the closer a local anesthetic is administered to an intended site of action and the higher the concentration of drug that is used will lead to faster onset times. With respect to physical–chemical properties, the pKa is a major determinant of the proportion of drug that is charged or uncharged in any solution, including body fluids. Since the uncharged (base) form of drug is more lipophilic and therefore better able to diffuse into the plasmalemmal membrane compartment of nerves, drugs with lower pKa values tend to have more rapid onset of action. For example, lidocaine and mepivacaine have lower pKa values than bupivacaine (Table 15.1) and, accordingly, exhibit more rapid rates of onset. Lower pKa values have a downside insofar as agents exist primarily as insoluble bases, such as benzocaine (pK = 2.5) where limited solubility renders it useful only for topical mucosal applications in most species, except fishes, where the drug's excellent tissue penetration provides significant benefit as an anesthetic agent.

Table 15.1 Comparative physical–chemical properties and pharmacological properties of three amino-amide class local anesthetics

Property	Lidocaine	Mepivacaine	Bupivacaine
Chemical structure				CASN 137-58-6	CASN 96-88-8	CASN 2180-92-9
Stereoisomers	No	Yes	Yes
pKa	7.8	7.7	8.1
Partition coefficient (λ) (octanol : water)	110	42	560
Water solubility (mg/l)	4100	7000	9.2×10^{-5}
Plasma protein binding	64%	80%	90%
Onset (~ min)	5–10 (fast)	10–20 (rapid)	20–30 (slow)
Duration (~ min)	90	130	360

* Indicates location of chiral center in mepivacaine and bupivacaine.

Lipophilicity and protein binding tend to reduce the ability of drugs to permeate nerve membranes and thereby delay the onset time for local anesthetic action. The duration of sensory nerve blockade by most agents is determined by multiple factors that are both extrinsic as well as intrinsic to the nerve cell membrane. Intrinsic factors within the nerve membrane microenvironment include the temporal profile of drug concentration at sodium channel binding sites, the balance between cationic and neutral forms of the drug, as well as the rates of drug association and dissociation from channel binding sites. Lipid solubility of individual agents is a primary determinant for drug distribution into membranes and directly influences the ability of local anesthetics to achieve effective concentrations at target binding sites. In addition, the binding affinity between individual agents and sodium channel subunits is critically important for determining duration of nerve blockade, since higher affinities are associated with slower rates of dissociation for the drug–receptor complex. As noted above, drug binding affinity to sodium channels also contributes to differences among individual agents with respect to the kinetics of channel blockade and nerve firing rate. In general, agents that display faster rates of dissociation from Na^+ channels have a greater impact on rapidly firing neurons compared to agents with slower rates of dissociation from channel binding sites.

In addition to intrinsic processes that influence the time course for local anesthetic action, other factors extrinsic to the nerve membrane can have a substantial impact on local anesthetic action. For most local anesthetics, contact time with sensory nerves is of primary importance and is directly dependent on local blood flow. Passive diffusion of local anesthetic into blood vessels in the vicinity of the injection site(s) represents the primary pathway for drug removal and thereby determines the time course for drug exposure to nerves and other potential target sites. As pointed out in Section Clinical Uses in Veterinary Medicine, local blood flow can be, and frequently is, manipulated intentionally by coadministration of vasoconstrictor agents, which reduce regional blood flow and thereby prolong the period of anesthetic action. In clinical practice, epinephrine is used most commonly as a vasoconstrictor agent and is included in some commercial preparations at a low concentration (typically 5 parts per million or 1 : 200,000). In practical terms, vasoconstrictors serve two purposes by reducing drug movement into the vascular compartment and reducing the risk of systemic toxicity. In this way, drug residence near the intended site for action is prolonged and the rate of drug metabolism is better able to keep pace with drug absorption into the circulation.

In conjunction with these benefits, there is some potential for added risk from the use of vasoconstrictors, including untoward cardiovascular changes and other reactions associated with excessive systemic absorption or accidental intravascular injection of the vasoconstrictor agent. In addition, there is some potential for delayed wound healing, tissue edema, tissue hypoxia, and necrosis when local anesthetic/vasoconstrictor preparations are administered in multiple sites or within digits, limbs, or other body regions that have limited collateral circulatory supplies. For this reason, vasoconstrictors are contraindicated in applications (e.g., ring blocks) where there is risk of compromised blood supply. One final concern, relates to the administration of epinephrine in body regions where blood vessels are preferentially dilated rather than constricted by mixed-acting adrenergic agents (i.e., mixed α/β agonists) such as epinephrine. In tissues such as skeletal muscle, the predominant effect by epinephrine on vascular smooth muscle is relaxation, which is a direct consequence of an overriding response to β_2-receptor activation (relaxation) versus α_1-receptor activation (contraction). Under such conditions, local blood flow is increased and systemic absorption of local anesthetic may also be increased, thereby increasing the risk for adverse effects. In order to avoid this unwanted consequence, epinephrine should either not be used or replaced with a different vasoconstrictor agent, such as phenylephrine, that preferentially stimulates α_1-adrenergic receptors and presents little risk for a vasodilatory action. Several local anesthetics that are used clinically have some capacity to cause vasoconstriction of their own accord, including bupivacaine and ropivacaine. Cocaine, the classical local anesthetic agent, is the most potent vasoconstrictor local anesthetic owing to its ability to competitively inhibit catecholamine transporters and potentiate the actions of most endogenous catecholamines, including epinephrine and norepinephrine.

General ADME Considerations

As local anesthetics are absorbed from the extracellular fluid at injection sites, agents are subject to several potential fates as they enter the systemic circulation. Once in the bloodstream, some local anesthetics undergo extensive binding with plasma proteins, notably α_1-acid glycoprotein and, to a lesser extent, serum albumin. Local anesthetics exhibit high binding affinity with the former, but the capacity is low and can be saturated readily. In contrast albumin provides a large capacity for drug binding, but binding is lower affinity and may have limited relevance except at very high drug concentrations. While the plasma protein binding properties of individual local anesthetics have not been fully delineated across most animal species, based upon human data it is suspected that agents in the amino amide class are highly bound to plasma proteins(up to 95%) whereas most ester-linked local anesthetics are not highly bound. For amino-amide agents such as bupivacaine and ropivacaine, where the protein-bound fractions of drug are high, small reductions in protein binding hold the potential to produce significant adverse consequences owing to the corresponding large shift in the fraction of free drug. As true for any drug that is highly bound to plasma protein, binding of local anesthetics may be influenced through several possible means, including competitive displacement by drugs or endogenous substrates that bind with high affinity to the same classes of serum proteins, changes in plasma pH that cause a shift in drug–protein interactions, or changes in serum proteins associated with conditions or diseases that affect levels of plasma proteins per se. For example, several factors have been reported to increase circulating levels of α_1-acid glycoprotein in humans (cancer, surgery, trauma, myocardial infarction, and uremia), and it is possible that similar changes may take place in nonhuman species. Since most systemic actions of local anesthetics are unwanted and considered adverse in a clinical setting, it is prudent to consider such factors that can impact the free concentration of diffusible drug in clinical patients.

Metabolic degradation of local anesthetics is arguably the preeminent consideration with respect to potential adverse effects by local anesthetics that are used in routine veterinary practice. In general, adverse reactions to local anesthetics are closely associated with circulating drug concentration, which is a direct reflection of the balance between the relative rates of drug absorption and drug elimination. Once absorbed from an injection site, local anesthetics are subject to enzyme-catalyzed metabolism or available to diffuse into tissues where the drug may produce untoward reactions. For this reason, care must be taken to avoid direct intravascular administration of a high concentration of local anesthetic, since the rapid intravascular delivery is likely to overwhelm metabolic processes and pose substantial risk of adverse effects. For agents that contain an amino-ester linkage (i.e., cocaine, benzocaine, procaine, and tetracaine), enzymatic metabolism most commonly follows initial catalytic hydrolysis of the ester link by different families of esterase enzymes, including plasma cholinesterases, acetylcholinesterase, and nonspecific esterases in liver and other tissues. In all cases, it appears that hydrolysis of the amide-ester linkage causes loss of local anesthetic activity. In animals with deficient or abnormal esterase enzyme activities or following exposure to agents that inhibit these enzymes, amino-ester linked local anesthetics can display more intense or prolonged actions. In the case of local anesthetic injections into the intrathecal space, amino-ester local anesthetics can exhibit prolonged actions since CSF normally contains no esterase enzymes and termination of drug action relies primarily on absorption back into the general circulation.

It is important to note that one of the by products from procaine metabolism is para-aminobenzoic acid (PABA), which has the potential to compete with and attenuate the antimicrobial actions of sulfonamide antibiotics. In addition, procaine may provoke allergic reactions in animals that are sensitive to sulfonamide-class agents. In contrast to the ester-type agents, metabolism of the amino-amide class of local anesthetics occurs through hepatic biotransformation, although specific pathways have not been fully elucidated in all domestic species.

The most common pathway for hepatic metabolism of amino-amide local anesthetics involves initial *N*-dealkylation followed by additional metabolic transformations. Lidocaine metabolism is perhaps best described and proceeds via oxidative dealkylation by liver cytochrome P450 (CYP) enzymes to form monoethylglycinexylidide (MEGX) and glycinexylidide (GX) as well as additional secondary products. Cleavage of the amide bond in agents that contain a pipecolyl moiety (mepivacaine, bupivacaine, and ropivacaine) proceeds at a slower rate due to chemical hindrance by the bulky alkyl groups surrounding the piperidine nitrogen, which gives rise to the longer biological half-lives for these agents. In view of the importance of hepatic metabolism for elimination of the amino-amide local anesthetics, animals with liver disease may exhibit a reduced capacity to eliminate these agents. Metabolic handling and excretion of urinary metabolites of several local anesthetics has been studied in horses owing to regulatory concerns related to use of these agents in racing animals (Harkins et al., 1995). Urinary excretion of unmetabolized drug appears to be limited and variable and has been reported to account for only 2–5% of lidocaine and bupivacaine and slightly more than 10% of mepivacaine in humans.

Drug Interactions

The potential for drug interactions is an important consideration in the decision to use or selection of a local anesthetic agent. While some interactions are undesirable, not all are problematic. Many interactions are agent specific whereas others appear to be more general for the entire class of agents. Pharmacological interactions between local anesthetics and other drug classes include both pharmacodynamic and pharmacokinetic interactions and, in many cases, are reliant on systemic drug levels that are associated with systemic administration, such as constant rate infusion rather than the more typical route(s) used to produce a local anesthetic effect. Among the most studied and documented interactions is the capacity of lidocaine to lower the required general anesthetic doses of isoflurane in cats, dogs, and horses (Himes et al., 1977; Doherty and Frazier, 1998; Muir et al., 2003).

Organ Toxicities

In view of the capacity of local anesthetics to exert actions on voltage-activated sodium channels in cell membranes of excitable tissues, it is not surprising that the major adverse effects of these drugs occur within organ systems that are highly dependent on cellular electrical activity, namely the central nervous and cardiovascular systems. As depicted in Figure 15.4, signs of local anesthetic-induced adverse effects progress from initial effects in the CNS and, at higher plasma concentrations, expand to involve other organ systems, notably the CVS. The most effective means to diminish the risk for local anesthetic toxicity is to take steps to maintain a low plasma drug concentration and, in that regard, the most important consideration is dose. The amount of drug administered and the time frame over which it is given is a primary risk factor for local anesthetic toxicity and is likely why toxicity occurs more frequently in small animals, in which recommended dose limits may be exceeded when drug is administered repeatedly in small increments. As discussed previously, steps should be taken to minimize vascular absorption, including use of vasoconstrictors, avoiding highly vascularized sites when practicable, and taking care to avoid direct intravascular drug administration. In clinical approaches where there is deliberate intravascular injection (e.g., IVRA), toxicity can be avoided as long as sufficient time is allowed for drug to bind with tissues before the tourniquet is released. Care must be used with local anesthetic injections into the intercostal space since this region is highly vascularized and provides a site for rapid drug absorption.

Central Nervous System

The ability of local anesthetics to produce rapid adverse neurological effects is a major concern. In most cases, local anesthetics produce generalized descending CNS depression that is proportional to the free (unbound) circulating concentration of drug. The earliest signs in animals frequently involve subjective minor behavioral changes followed by muscle twitching and tremors that may occur initially in facial musculature (twitching of lips, movements of whiskers, etc.) but spread rapidly to become full tonic–clonic convulsions. Although the sequence of adverse signs differs somewhat among various agents, the sequence of events is suspected to follow effects that arise initially from brain regions that are most highly vascularized (limbic regions) and equilibrate with drug in plasma most quickly. In the case of lidocaine, initial twitching and convulsions is believed

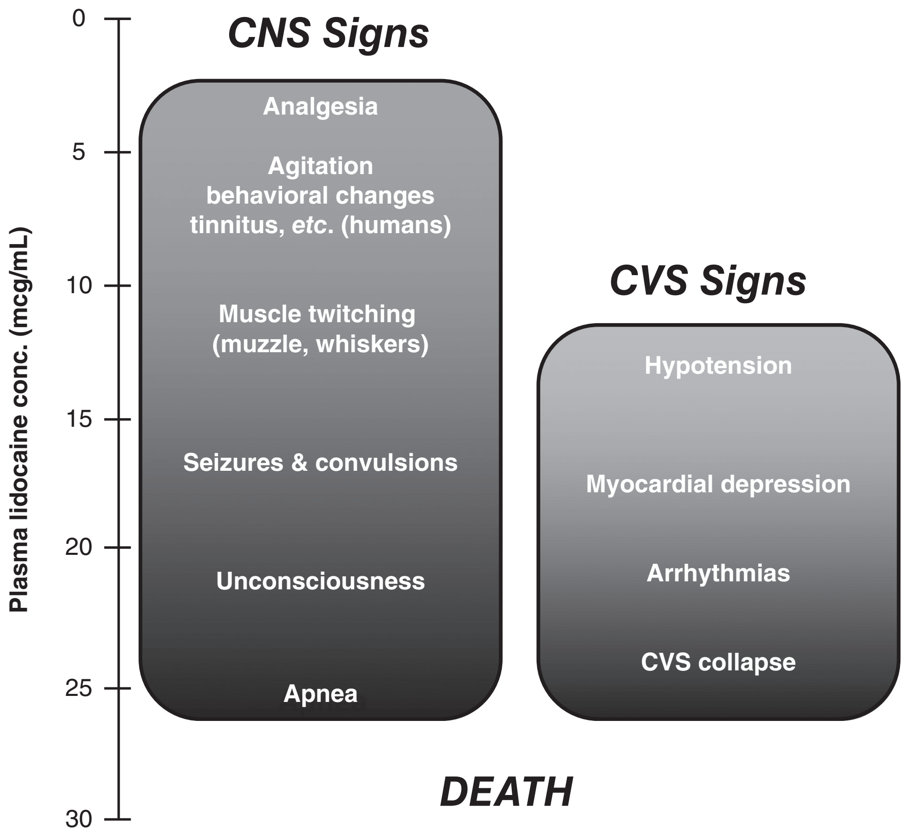

Figure 15.4 Representation of adverse effects from lidocaine in the central nervous system (CNS) and cardiovascular system (CVS) as a function of plasma drug concentrations in the dog.

to arise from initial preferential blockade of inhibitory pathways, rather than any direct excitatory actions that can occur with cocaine. Differences in the acute toxicities of individual agents are likely a reflection of differences in the concentration of free drug that is achieved within the CNS, which is dependent on the rate of drug passage through the blood–brain barrier as well as the rate of drug metabolism. Metabolism tends to be less important for amide-linked agents but can be a significant factor for the ester-linked local anesthetics, which are readily metabolized by plasma esterases. In general, the greater lipophilicity and higher plasma protein binding of amide-linked agents, particularly bupivacaine, can give rise to blunted and transient peak plasma drug concentrations, which may explain in part why such agents are less likely to produce adverse CNS signs initially. If CNS signs occur following local anesthetic administration, symptoms are managed through various means, including a higher concentration of supplemental oxygen and intravenous administration of a benzodiazepine or other anticonvulsant agent in order to control seizures.

Cardiovascular System

Cardiovascular toxicity by local anesthetic agents is complex and involves direct mechanical and electrophysiological effects on the myocardium as well as direct and indirect effects on physiological processes that control peripheral circulation. The primary adverse signs of local anesthetic effects in the CVS are a drop in blood pressure with reduced tissue perfusion and cardiac dysrhythmias. As shown in Figure 15.4, CVS changes caused by lidocaine develop at higher plasma drug concentrations as compared to adverse CNS signs, although that is not the case for racemic bupivacaine, which is substantially more cardiotoxic than lidocaine. With regard to lidocaine, severe hypotension arises from several underlying causes, including depressed myocardial contractility with reduced cardiac output, direct relaxation of vascular smooth muscle, and a generalized loss of vasomotor sympathetic tone. Enhanced cardiovascular sensitivity to bupivacaine appears to derive in part from its higher lipophilicity and different binding kinetics to cardiac sodium channels. Electrophysiological studies have revealed that bupivacaine binds more rapidly than lidocaine with open myocardial sodium channels during membrane depolarization associated with an action potential (systole). However, unlike lidocaine, which dissociates from channel binding sites during diastole, bupivacaine remains bound owing to a slower rate of dissociation from the channel complex. Accordingly, as heart rate increases, a greater fraction of channels remain occupied by bupivacaine, giving rise to significant electrophysiological consequences. The basis for myocardial toxicity by bupivacaine is shared with etidocaine, which causes similar problems from reentrant arrhythmias. In animals that develop cardiovascular depression or collapse, clinical management requires both ventilatory and cardiovascular support, which may include atropine in animals with severe bradycardia. Several controlled trials have indicated that the success rate for resuscitation of dogs suffering from bupivacaine-induced cardiac collapse is substantially less than dogs in which the causative agent is lidocaine (Groban et al., 2001; Picard and Meek, 2006).

Regulatory Considerations

At present there are only three products that are granted approval by the Food and Drug Administration (FDA) Center for Veterinary medicine (CVM) for specific use as local anesthetics in nonhuman species. Mepivacaine (Carbocaine-V®, NADA 100-703), is approved for use in horses, but not in horses intended for human consumption. Proparacaine (Ophthaine®, NADA 009-035), has the unusual designation of "unspecified (animals)" as the target animal species. This unspecified designation is a holdover from the former approval system that is still in place for products that were approved many years ago. Lidocaine is the only other local anesthetic that has been granted FDA-CVM approval for use in dogs (Lidocaine Hydrochloride with Epinephrine Injection 2%, NADA 045-578), although that particular product was withdrawn voluntarily by the sponsor many years ago. There are several approved veterinary products in which local anesthetic agents are formulated in combination with other active ingredients, notably procaine, tetracaine, and lidocaine. However, none of these products are indicated for specific use as local anesthetics in the approved species. Combination products that contain procaine and penicillin G are known to be a source of problems in performance and racing animals owing to regulatory testing for procaine as a regulated substance. Local anesthetics are classified as Class 2 substances by the Association of Racing Commissioners International (ARCI) owing to their potential for masking pain. Detection of these drugs or their derivatives in postrace urine samples can result in substantial penalties, including fines, suspensions, and license revocation. The absence of any FDA-approved local anesthetics for use in food-producing animal species is somewhat problematic, since there are many occasions where such agents are needed to control pain. While this remains one of many areas that is not addressed specifically by any federal statute, the FDA regards the use of local anesthetics in food-producing species to be of low regulatory concern. Nevertheless, since the use of any local anesthetic in a food animal constitutes extralabel drug use, such use must be accompanied by a scientifically derived extended withdrawal time to assure the absence of any unsafe residues in human food products. In view of the relatively short half-life of lidocaine in most species, the Food Animal Residue Avoidance Databank (FARAD) has recommended withdrawal intervals of 24 hours in meat and milk following epidural administration (up to 15 ml of 2% solution) in cattle and longer withdrawal intervals of 72 hours (milk) and 96 hours (meat) following subcutaneous infiltration of lidocaine (inverted L block, up to 2 g) in cattle. These recommendations are based in part on a study by Sellers and colleagues (2009). The following discussions of individual local anesthetics focus on agents that are used most commonly in clinical veterinary practice.

Lidocaine

Lidocaine is the original and prototypical amino-amide local anesthetic that continues to be the most widely used local anesthetic agent in veterinary practice. The widespread popularity of lidocaine is attributable to several pharmacological and nonpharmacological features, including its low cost, long shelf life, chemical stability, heat tolerance, and availability in a multitude of therapeutic formulations. Lidocaine possesses a good pharmacological profile, including rapid onset (2–5 min), an intermediate duration of action (20–40 min), and lower systemic toxicity than bupivacaine. In animals that are sensitive to amino-ester local anesthetics, lidocaine is the agent of choice. Lidocaine is absorbed rapidly following most routes of administration and, therefore, it is combined frequently with epinephrine or another vasoconstrictor agent in order to reduce intravascular absorption of drug when administered by a nonvascular route. In addition to its well-recognized actions as a local anesthetic, lidocaine has been used clinically in both small and large animal species to treat ventricular tachyarrhythmias (Class 1B antiarrhythmic agent) and has been investigated for potential therapeutic uses to mitigate tissue reperfusion injury associated with hypoxia, especially in the treatment of equine postoperative ileus as well as other possible applications for gastrointestinal disorders (Cook and Blikslager, 2008). Several additional applications for lidocaine remain largely investigational at this time although they hold good promise for expanding the clinical use of lidocaine, including treatment of inflammation secondary to multiorgan dysfunction syndrome (Cassutto and Gfeller, 2003), generalized control of pain in dogs, cats, and selected large animal species, as well as adjunctive use for decreasing the requirement for general anesthesia, notably inhalation anesthetic agents. Although there are limited evidence-based clinical benefits that have been demonstrated for these or other uses of lidocaine, this drug remains the subject of significant clinical interest and research. Many of these and other therapeutic applications of lidocaine are addressed in greater detail elsewhere in this text and other publications.

The metabolic fate and pharmacokinetics of lidocaine has been investigated in many nonhuman species. In general, lidocaine undergoes rapid hepatic aminodealkylation by CYP enzymes, which gives rise to relatively short terminal half-lives of less than 1 hour for the parent drug in most domestic species. Hepatic metabolism of lidocaine has been described in great detail in humans and dogs wherein there is an initial formation of two major metabolites, notably monoethylglycine xylidide (MEGX) and glycine xylidide (GX), which consequently undergo additional metabolic transformation into monoethylglycine and xylidide, respectively. In humans, approximately three-fourths of the xylidide metabolite is excreted in urine as 4-hydroxy-2, 6-dimethylaniline. Both MEGX and GX retain some capacity to block sodium channels and, thereby, may contribute to the spectrum of pharmacological effects produced by lidocaine, especially in situations where it is administered over a prolonged period of time (e.g., constant rate infusion) that may cause significant accumulation of active metabolites. While the clinical relevance of pharmacological actions by lidocaine metabolites remains unclear, several studies point to new possible roles or applications in humans and nonhuman species. A study in cultured glial cells from the CNS of rats has revealed a novel action for both MEGX and GX, specifically their ability to act as potent inhibitors of glycine transport. In view of the major inhibitory role of glycine as a CNS neurotransmitter, this effect by lidocaine metabolites has been postulated to contribute in part to the analgesic actions produced by systemic lidocaine administration (Werdehausen et al., 2012). In addition, the rate of hepatic lidocaine clearance and formation of MEGX from lidocaine has been demonstrated to provide a dynamic liver function test in humans with liver disease or reduced hepatic blood flow and has been evaluated for similar application in dogs (Neumann et al., 2011; Pérez-Guillé et al., 2011). Therefore, although lidocaine is one of the oldest local anesthetic agents that remains in clinical use, there may yet be more that can be learned from continued studies of the actions of this old mainstay drug.

At plasma concentrations in the low microgram per milliliter range, lidocaine causes acute adverse signs in most species, including humans. While there appear to be some species differences with regard to plasma lidocaine levels that give rise to these signs and symptoms, the sequence and progression of lidocaine toxicity appears fairly similar in humans and many domestic animal species. Initial signs of lidocaine toxicity appear as CNS toxicity and are reported in humans to include drowsiness, tinnitus, disturbances in taste (dysgeusia), dizziness, and muscle fasciculation (twitching). While the latter sign is the only overt symptom that may be readily apparent in nonhuman species, some of the nonspecific behavioral changes attributed to lidocaine toxicity may be a reflection of CNS signs, which frequently dissipate within several minutes when associated with a single bolus injection of lidocaine. In dogs and horses, the window of safety between plasma levels that are effective in controlling cardiac arrhythmias and those that cause acute CNS signs is fairly narrow, and has been reported to be two to threefold. At higher plasma lidocaine concentrations, CNS signs become more pronounced and are accompanied by signs of cardiovascular toxicity, including hypotension and myocardial depression. As the circulating levels of lidocaine increases, seizures, coma, and respiratory depression and arrest will occur. As noted above, the lidocaine metabolites MEGX and GX may contribute in part to these side effects, especially when lidocaine is administered over a prolonged period.

Among local anesthetics that are used in veterinary medicine, lidocaine is noteworthy for being administered by the greatest diversity of administration routes. The diverse uses of lidocaine are likely attributable in part to the wide array of human drug formulations that are available as both prescription and over-the-counter products. Although there are a very limited number of lidocaine products that are approved specifically for nonhuman species, veterinary practitioners have used the full spectrum of human lidocaine formulations that have been developed for topical, ophthalmic, mucosal, and transdermal uses in humans. For topical applications, lidocaine is considered to be most effective when applied to mucous membranes and far less effective on intact skin. Nevertheless, a combination product that contains equal concentrations (2.5%) of lidocaine and prilocaine (a eutectic mixture of local anesthetics or EMLA®) has been used to improve drug penetration through intact skin in several companion animal species (Erkert and MacAllister, 2005), although some problems have been reported in cats. Other formulations for topical application include gels, ointments, viscous solutions, and sprays. Perhaps the most widely studied means for topical administration of lidocaine are human products designed for transdermal delivery (e.g., Lidoderm patch). Pharmacokinetic analyses have been carried out with transdermal lidocaine patches in several companion animal species, including dogs (Ko et al., 2007), cats (Ko et al., 2008), and horses (Bidwell at al., 2007). Although transdermal delivery of lidocaine in horses has been reported to be limited, a report has suggested some novel approaches for enhancing delivery in this species (Stahl and Kietzmann, 2014). In spite of the disparate and somewhat contradictory findings regarding the efficacy of lidocaine following topical application, this approach continues to be used fairly routinely for postsurgical pain relief and other applications.

Bupivacaine

Bupivacaine is among the most potent and longest acting of the amino-amide local anesthetics that are used in veterinary practice. Along with levobupivacaine, mepivacaine, and ropivacaine, all of which contain a pipecolyl xylidide (PPX) moiety, bupivacaine is a highly lipophilic agent, a property that likely contributes to its high potency and extended duration of action relative to lidocaine. Owing to the presence of a chiral center within the PPX moiety, bupivacaine exists as stereoisomers that are designated as S(-) and R(+) isomers, respectively. Bupivacaine is frequently the drug of choice in situations that require use of a long-acting agent, even though it has a slow onset relative to lidocaine, with complete blocks taking 30 min or longer. The longer duration of action (5–8 hours) coupled with a possibly lower tendency to produce motor inhibition makes it advantageous for infiltration anesthesia, nerve blocks, intrapleural administration, as well as spinal and intrathecal techniques. In female human patients, it has been reported that both bupivacaine and its less toxic S(-) stereoisomer, levobupivacaine, appear in breast milk at concentrations approximately one-third of plasma drug concentrations following epidural anesthesia (Bolat et al., 2014). In view of the propensity of bupivacaine to produce adverse cardiovascular effects, which is a significant concern in human patients, this agent is contraindicated for use in IVRA applications, where there may be a significant risk of a rapid increase in plasma drug concentration. Bupivacaine is relatively ineffective when applied topically on skin or mucous membranes and, accordingly, is not administered in that manner. Pharmacokinetic studies with bupivacaine in dogs reveal a longer terminal half-life (30–60 min for IV bolus or brief infusions), although much longer half-lives have been reported following prolonged IV infusions or epidural administration. While bupivacaine elimination is slower than lidocaine and is markedly influenced by dose and route of administration, the prolonged duration of sensory blockade by bupivacaine is substantially longer than would be predicted from differences in the pharmacokinetic profiles of the two drugs. The basis for this prolonged action in some species, as well as a reported proclivity to block sensory nerves longer or more effectively than motor nerves, has led to significant research into the potential basis for these effects.

In contrast to the aforementioned advantages of bupivacaine, the most significant drawback to its use is a heightened risk of acute cardiovascular toxicity, which is cited as a significant concern in human patients. In small animal patients, CVS signs are manifest clinically as moderate to severe ventricular arrhythmias and myocardial depression, especially following inadvertent intravascular administration. Although both lidocaine and bupivacaine rapidly block cardiac Na^+ channels during systole, bupivacaine dissociates from channel binding sites at a slower rate during diastole as compared to lidocaine. This kinetic difference in drug binding is likely to give rise to prolonged blockade of a higher fraction of myocardial Na^+ channels at the end of diastole (Clarkson and Hondeghem, 1985). Thus, the block by bupivacaine is cumulative and substantially greater than would be predicted based upon drug concentration and its local anesthetic potency. At least some component of the adverse cardiac effects of bupivacaine appear to be mediated via actions within the CNS, since direct intracerebral injection of bupivacaine in the medulla can evoke malignant ventricular arrhythmias (Thomas et al., 1986). The clinical management of bupivacaine-induced cardiac toxicity can be very challenging, especially in patients that suffer coexisting respiratory changes with associated acidosis, hypercarbia, and hypoxemia. In addition to these adverse cardiovascular signs, racemic bupivacaine displays some propensity to elicit adverse CNS signs that are similar to signs produced by lidocaine. However, unlike lidocaine, the use of diazepam for treatment of seizures associated with bupivacaine toxicity has been questioned, since both drugs compete for mutual plasma protein binding sites, which could elevate plasma concentrations of free or unbound drug (Moore et al. 1979; Thomas et al., 1976). As discussed above, the most effective means to lessen risk of toxicity with any of the local anesthetics is to limit the total cumulative drug dose that is given to a patient. In this regard, upper dose limits recommended for bupivacaine in dogs (2–3 mg/kg) are lower than the recommended limits for lidocaine (6–10 mg/kg). Recommended limits for both drugs are reduced by 25–50% for cats.

Levobupivacaine

Levobupivacaine is the purified S(-) stereoisomer of racemic (R(+)/S(-)) bupivacaine that was developed, tested, and ultimately marketed and sold in an attempt to diminish the risk of CVS toxicity that had been observed in human patients treated with products containing the racemic mixture. In numerous experimental models involving a range of animal species, levobupivacaine has been found to be less toxic than racemic bupivacaine by as much as 30–60% (see review by Foster and Markham, 2000). Several lines of evidence point to a reduced risk of cardiotoxicity for levobupivacaine compared with R(+)-(*dextro)*-bupivacaine or racemic bupivacaine, including reduced overall effects or lower potencies with respect to blockade of cardiac sodium channels in the inactivated state, blockade of cardiac potassium channels, reduction in the maximal rate of cardiomyocyte depolarization, slowing of atrioventricular impulse conduction speed, and lengthening the duration of the QRS interval. In addition to the stereoselective actions of bupivacaine in cardiac tissues, there is evidence that bupivacaine uptake into the CNS may be enantio-selective insofar as intravenous injections of high (arrhythmogenic) doses of dextrobupivacaine in anesthetized rats have been shown to cause more rapid inhibition of neuronal firing in the nucleus tractus solitarius compared to equivalent doses of levobupivacaine (Denson et al., 1992). Other observations are consistent with enantio-selective CNS actions by bupivacaine stereoisomers, including evidence for a greater frequency of apnea and death in lab animals given dextrobupivacaine compared to equivalent doses of levobupivacaine and a significantly lower threshold for convulsions in sheep with the *dextro* isomer compared to the *levo* isomer (85 ± 11 vs. 103 ± 18 mg; Huang et al., 1998). Finally, a study by Gomez de Segura and colleagues (2009) in dogs suggests that levobupivacaine produces a shorter duration of motor neuron blockade compared to racemic bupivacaine.

Other Selected Agents

Mepivacaine

Mepivacaine is an amide-type local anesthetic with potency and toxicity slightly above that of lidocaine. Although it is the only parenterally administered local anesthetic approved by the FDA (horses), it is not used widely in veterinary medicine. Its unique role has been its use in equine limb blocks where mepivacaine's apparent ability to diffuse though tissue surrounding the injection site creates less edema following drug injection (Bishop, 1996).

Ropivacaine

Ropivacaine (Naropin) is a long-acting amide-type local anesthetic that has efficacy and potency nearly as high as bupivacaine and levobupivacaine but has lower CNS and CVS toxicity. The name ropivacaine has been used to refer to both the racemic mixture as well as the pure S(-) enantiomer. Owing to its expense and availability, ropivacaine is not used commonly in veterinary practice aside from selected reports of uses in dogs and horses. The drug has been reported to produce concentration-dependent effects on peripheral blood vessels, with vasoconstriction at low concentrations

(<0.5% w/v) and vasodilation at concentrations greater than 1 w/v% (Cederholm et al. 1992).

Proparacaine

Proparacaine is an ester-type local anesthetic that is one of two agents approved and marketed specifically for ophthalmic use. The sterile solution (0.5% w/v) is pH adjusted in order to minimize corneal irritation. In general, proparacaine has a faster onset and shorter duration of action than tetracaine, although the half-time for action is longer in dogs (45 min) than cats (15 min).

Procaine

Procaine has historical significance as being the first local anesthetic that was synthesized by chemists. Although it has moderate to low potency and little ability to penetrate mucous membranes, procaine provided evidence that it was possible to produce local anesthesia without the high risk of toxicity and abuse potential that occurs with cocaine. It is rapidly metabolized by plasma cholinesterases into PABA and diethyl-amino ethanol, with the former giving rise to allergic reactions in sensitive animals. The major use of procaine is in the combination with penicillin G to form an insoluble salt that provides slow release and sustained absorption of the antimicrobial drug.

Tetracaine

Tetracaine (Amethocaine) is a derivative of procaine that is approximately 100-fold more potent. It is used primarily for spinal anesthesia and topical anesthesia of the cornea. In ophthalmic applications, it is much longer lasting than proparacaine, even though it can be metabolized rapidly by deesterification.

Benzocaine

Benzocaine is a unique local anesthetic insofar as its use is restricted to topical applications. It has the lowest pK of all local anesthetics that are used clinically, which renders the drug completely unionized at physiological pH. Benzocaine is useful in aquatic species since it can be absorbed readily through the fish's gills and produce general anesthesia. At higher doses, anesthesia can progress to death and benzocaine has been used for chemical euthanasia in fishes. An older use of benzocaine was a laryngeal spray formulation to facilitate airway intubation in cats, but that has been discontinued owning to methemoglobinemia caused by the metabolite benzoic acid.

Future Outlook

There are many areas for potential improvements and expansion of the clinical uses for local anesthetic agents, especially with respect to the pharmacological management of chronic pain. As is true for almost any class of therapeutic agents, there is an ongoing search for better and safer drugs with improved properties related to their spectrum of action, diminished side effects, improved safety profile, and duration of action. With regard to the local anesthetics, development of topically applied agents with rapid onset would be a significant advance insofar as such agents could have reduced systemic side effects and potentially be effective for long-term treatment of localized chronic pain. With further refinement of existing drugs or the development of novel agents, topical analgesics could offer relief for chronic pain conditions that are currently challenging to treat, such as pain resulting from burns, wound debridement, and other conditions. With continued advances in targeted drug-delivery systems, topical analgesics may be able to provide a method to prevent or mitigate phenomena that are difficult to manage clinically, including peripheral or central sensitization as well as neuroplastic changes that may be responsible for the transition from acute to chronic pain states in patients. In this regard, there may be opportunities for targeting novel molecular sites that are distinct from neuronal sodium channels. In addition, the rich and diverse array of sodium channels in different classes of nerves and excitable tissues present some potential for identification of agents that exert selective actions on molecular targets in sensory nerves that transmit pain impulses, without affecting sodium channels in other classes of sensory neurons as well as motor neurons. In this regard, the discovery that selected local anesthetics are able to cross nerve membranes and gain access to target sites within sodium channels by passage through a family of cation-selective membrane channels (TRPV-1 channels) offers an avenue for greater functional selectivity by these agents. Since TRPV-1 and other membrane channels are selectively expressed in selected classes of peripheral sensory neurons, there is potential to develop analgesics that utilize this pathway to exert improved selectivity for pain transmission pathways. Beyond that, entirely new molecular targets could be identified for actions of these drugs. As noted in Section Lidocaine, several metabolites of lidocaine have direct influence on transporters for the inhibitory neurotransmitter glycine in the spinal cord. Since it is recognized that inhibitory glycinergic neurotransmission is impaired in chronic pain states, this or related molecular targets may provide an opportunity for new drug development. Inhibitors of the glycine transporter 2 (GlyT2) are known to enhance inhibitory neurotransmission and have shown particular promise for the treatment of neuropathic pain (Vandenberg et al., 2014). These are just a few of the many examples of opportunities for important new developments with local anesthetics and serve to underscore the need for continued research into effective means to treat patients, both human and nonhuman, with treatment-resistant pain.

Euthanizing Agents

Anna Hampton

Introduction

Euthanasia is derived from the Greek terms *eu* (good) and *thanatos* (death) and is considered a method to end an individual's life as rapidly as possible with little to no pain or distress associated with the procedure (American Veterinary Medical Association, 2013; Close et al., 1996, 1997). In order to be considered euthanasia, the procedure must result in rapid loss of consciousness, followed by loss of vital body functions (respiration, heartbeat, and brain function). It is crucial that euthanasia be performed with consideration of the animal's welfare and with the highest degree of respect. In addition, all aspects of euthanasia, not just the method chosen, should be evaluated to ensure that pain and distress are minimized. This includes preeuthanasia procedures such as handling, restraint, and the environment, as well as confirmation of death (Canadian Council On Animal Care in Science, 2010; United Kingdom House of Commons, 1986). Furthermore, it is prudent that the animal's remains and euthanasia solutions are used and disposed of appropriately and legally (American Veterinary Medical Association, 2013).

Euthanasia methods for animals can be divided into two primary groups (chemical and physical methods) and three basic mechanisms (direct depression of neurons vital for life functions, hypoxia, and physical destruction of neurons and brain activity vital for life). This chapter solely focuses on the pharmacology of chemical methods of euthanasia. Regardless of the group, the following items should be considered on a case-by-case basis when choosing a method of euthanasia, as outlined by the AVMA *Guidelines for the Euthanasia of Animals*: *2013 Edition*, and other core documents (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010; Close et al., 1996, 1997; United Kingdom House of Commons, 1986):

- ability to induce loss of consciousness and death with a minimum of pain and distress;
- time required to induce loss of consciousness;
- reliability and reproducibility;
- safety of personnel;
- training of personnel for all aspects;
- required restraint and handling;
- ease of administration;
- irreversibility;
- compatibility with species, age, and health status;
- compatibility with intended animal use and purpose;
- compatibility with subsequent evaluations, examinations, or use of tissue;
- drug availability and human abuse potential;
- ability to maintain equipment in proper working order;
- safety for predators or scavengers should the animals remains be consumed;
- legal requirements;
- environmental impacts of the method and disposition of the animal's remains;
- emotional effect on observers or operators.

It is essential that personnel are educated and trained in the appropriate and safe techniques for all aspects of euthanasia, which includes preeuthanasia handling and restraint, and understand the underlying justifications for euthanasia. This not only aides in the humane treatment of animals, ensuring as little distress as possible, but can also help mitigate any psychological impacts on the individual (caring–killing paradox) (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010). In addition, if the method chosen involves controlled substances, it is important to institute proper storage and diversion control to prevent abuse, and in some cases suicide. Most euthanasia agents have a narrow therapeutic index or excessive side effects and are not used in human medicine. Acepromazine, xylazine, T-61, barbiturates, and others have been used in suicide or suicide attempts (Perri, 2015; Giorgi and Bertini, 2000).

It is beyond the scope of this chapter to discuss animal slaughter or killing of wild game for sport.

Inhaled Agents

In general, inhaled methods of euthanasia fall into one of two mechanisms: (i) hypoxia and/or (ii) direct depression of neurons vital for life functions. It is imperative that crucial concentrations of the gases and vapors in the alveoli and blood are achieved to get the desired effect, rapid unconsciousness. Gas displacement, container volume, and gas concentration can all affect the time to onset of unconsciousness. Gases should be delivered in a calibrated and purified from; this is commonly accomplished through the use of a flow meter and/or pressure-reducing regulator (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010). Inhaled methods of euthanasia are not recommended for animals that are resistant to hypoxia or hold their breath like poikilotherms, diving animals, and neonatal animals (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010; Close et al., 1996, 1997; Pritchett et al., 2005; Pritchett-Corning, 2009). In addition, rabbits tend to be distress when exposed to gasses and other methods may be more appropriate for this species (Close et al., 1996, 1997). Although it can be difficult to determine if gas exposure is distressful to a specific species or individual, behavior while being exposed to the agent or aversion testing can provided some information. The results, as discussed in this section, can produce a large breath of recommendations for specific species or situations when using inhaled agents, which highlights the importance of choosing a method for specific situations and species. As a general recommendation, death should be confirmed by cession of vital signs or a definitive, secondary method of euthanasia should be performed to prevent recovery.

Carbon Dioxide

Inhaled carbon dioxide is likely one of the most studied and disputed euthanasia methods available. Because it is rapid, safe, inexpensive, and readily available it is the most common method of euthanasia for laboratory rodents (Artwohl et al., 2006). Respiratory exposure to CO_2 causes respiratory acidosis, which in turn creates a physiological domino effect. Acutely, this small molecule rapidly diffuses from the lungs into the plasma and intracellular spaces, and when combined with water it produces carbonic acid which rapidly splits into bicarbonate and hydrogen ions. If the buffering capacity is exceeded in this dose-dependent process you get respiratory acidosis. The resulting acidification of the intracellular space and cerebrospinal fluid leads to suppressed nerve cell function and inhibition of central *N*-methyl-D-aspartate (NMDA) receptors causing anesthesia (American Veterinary Medical Association, 2013; Close et al., 1996, 1997; Martoft et al., 2003; Pritchett et al., 2005; Thomas et al., 2012). Prolonged exposure to CO_2 and/or high concentrations of CO_2 then leads to severe respiratory acidosis and depression of the respiratory centers of the brain, eventually resulting in death. Other actions include acidosis-induced depression myocardial contractility and direct myocardium effects (American Veterinary Medical Association, 2013; Pritchett et al., 2005; United Kingdom House of Commons, 1986). Although eventual hypoxia results, it is not the direct mechanism of action resulting in death.

The ideal rate of CO_2 delivery appears to be species specific. For rodents, there has been conflicting reports with some recommending use of a prefilled chamber (100% CO_2) for euthanasia (Artwohl et al., 2006; Canadian Council On Animal Care in Science, 2010), while others recommend a gradual fill method, with a fill rate of approximately 10–20% of chamber volume per minute (American Veterinary Medical Association, 2013; Burkholder et al., 2010; Close et al., 1996, 1997; Conlee et al., 2005). Conflicting recommendations have also been published for swine and poultry (American Veterinary Medical Association, 2013; Close et al., 1996, 1997; Grandin, 1994). Furthermore, 100% exposure is recommended in rabbits and ferrets, but these animals may also be distressed at any exposure (Close et al., 1996, 1997; Fitzhugh et al., 2008). Regardless of the rate of delivery, use of compressed CO_2 gas in cylinders with flowmeters to precisely deliver the gas is the only acceptable source (American Veterinary Medical Association, 2013; Artwohl et al., 2006; Canadian Council On Animal Care in Science, 2010; United Kingdom House of Commons, 1986). Euthanasia can be accomplished over a wide range of concentrations (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010; Close et al., 1996, 1997; Leach et al., 2002; United Kingdom House of Commons, 1986).

Many studies have looked at effect of gas combinations to mitigate the negative aspects of CO_2 euthanasia, with variable results. It has been suggested that the addition of nitrous oxide to CO_2 decreases the time to unconsciousness in mice and pigs, thus likely decreasing the distress the animal experiences (Llonch et al., 2012; Rault et al., 2013; Thomas et al., 2012).

Respiratory acidosis and other physiological events that occur during exposure to CO_2 leads to successful euthanasia, but may also play a role in potential pain and distress an animal experiences when exposed to CO_2. Resulting lactic acidosis leads to activation of the acid sensing ion channels (ASIC), which may cause pain or fear (American Veterinary Medical Association, 2013; Thomas et al., 2012). In addition, as indicated earlier, carbonic acid is created when CO_2 combines with water. This reaction occurs in the ocular, nasal, and oral mucous membranes and carbonic acid activates polymodal nociceptors and has an irritating effect on these areas (American Veterinary Medical Association, 2013; Close et al., 1996, 1997; Hawkins et al., 2006; Leach et al., 2002; United Kingdom House of Commons, 1986). CO_2 also has a pungent odor and hypoxia may lead to a feeling of breathlessness, thus possible distress if unconsciousness is not rapid (American Veterinary Medical Association, 2013; Close et al., 1996, 1997; Hawkins et al., 2006; Leach et al., 2002). Because of carbonic acid production, CO_2 should not be dissolved in water to euthanize aquatic species (Canadian Council On Animal Care in Science, 2010). Some recommend that it not be used as a sole agent in species that have shown significant aversion to CO_2 exposure such as pigs, mink, ferrets, and rodents (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010; Conlee et al., 2005; Fitzhugh et al., 2008; Leach et al., 2002; Makowska et al., 2009; Valentine et al., 2012). However, other studies have shown that it can be used successfully in pigs and rodents (Burkholder et al., 2010; Grandin, 1994; Hackbarth et al., 2000; Sharp et al., 2006).

Since CO_2 exposure is the most common method of euthanasia for laboratory rodents, it is important to consider the biochemical effects and possible artifacts that may be created if this method of euthanasia is elected. CO_2 exposure can stimulate enzymes in the glycolytic pathway, and affect red blood cell parameters (Artwohl et al., 2006). In addition, lung pathological artifacts such as edema and hemorrhage have been reported (Danneman et al., 1997; Fawell et al., 1972).

Advantages of CO_2 as a euthanasia agent is that it is heavier than air so less likely to displace out of container (however, consider the height of the animal), generally has a rapid onset, is relatively inexpensive, and nonflammable and nonexplosive (American Veterinary Medical Association, 2013; Close et al., 1996, 1997; Llonch et al., 2012). However, the advantages must be heavily weighed with the substantial and conflicting reports on the potential for pain and distress with this method, which make it difficult to have generalized recommendations.

Carbon Monoxide

Carbon Monoxide (CO) is a colorless, odorless gas that is produced by the chemical interaction of sodium formate and sulfuric acid. It preferentially combines with the iron in hemoglobin producing carboxyhemoglobin, blocking uptake of oxygen and inhibiting other binding sites to off-load oxygen, resulting in hypoxia (American Veterinary Medical Association, 2013; Close et al., 1996, 1997; Makowska and Weary, 2009). This leads to loss of consciousness, eventually resulting in death. During loss of consciousness the motor centers of the brain are stimulated, thus this may be accompanied by convulsions and muscle spasms. In general CO produces rapid loss of consciousness and death with minimal pain and distress at low concentrations (4–6%), although this may be species dependent (American Veterinary Medical Association, 2013; Makowska and Weary, 2009). Use of a presedative may decrease the signs of distress in dogs (Dallaire and Chalifoux, 1985). The main concern with use of CO for euthanasia is the occupational risk involved to personnel. It is a human hazard and can be explosive in high concentrations. The environment should be equipped with an effective exhaust or ventilation system, CO monitors, and spark free and explosion-proof electrical equipment (American Veterinary Medical Association, 2013; Close et al., 1996, 1997). Only commercial cylinders should be used for euthanasia (Close et al., 1996, 1997).

Argon

Argon (Ar) is an odorless, colorless, and tasteless inert gas. It is nonflammable and nonexplosive. Its mechanism of action, producing unconsciousness and eventual death, is achieved by displacing air/oxygen causing anoxia. Production of unconsciousness is rapid if oxygen levels are <2% and gradual exposures are not recommended as they result in prolonged exposure to hypoxic conditions prior to unconsciousness, and resulting distress. It is important that death is confirmed before oxygen levels are reestablished to prevent recovery (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010). In general, euthanasia with Ar requires longer exposure times when compared to CO_2 and its use has been described in swine, poultry, and rodents. This being said, exposure response and aversion appears to be species dependent and anesthesia prior to exposure has been recommended (American Veterinary Medical Association, 2013; Burkholder et al., 2010; Canadian Council On Animal Care in Science, 2010; Close et al., 1996, 1997; Leach et al., 2002; Llonch et al., 2012; Makowska et al., 2009; Sharp et al., 2006).

Nitrogen

Nitrogen has very similar properties to argon, described in Section Argon. It produces death by the same mechanism as argon, displacement of air and subsequent anoxia with unconsciousness being reached if O_2 is <2%. It too has been described as a euthanasia agent in poultry, swine, and rodents, with species variability (American Veterinary Medical Association, 2013; Close et al., 1996, 1997; Llonch et al., 2012; Sharp et al., 2006). An important application of nitrogen asphyxiation is for mass emergency depopulation of commercial poultry operations (Benson et al., 2007; National Turkey Federation, 2013). This approach uses medium expansion water-based firefighting foams (nitrogen, water, foam concentrate). This has recently been applied in depopulation of flocks exposed to highly pathogenic avian influenza (HPVI).

Inhalant Anesthetic Overdose

An anesthetic is an agent that produces drug-induced depression of the nervous system, unconsciousness, analgesia, muscle relaxation, and absence of perception of all sensation, in a controllable manner. When an anesthetic overdose is given, it results in eventual cessation of vital signs resulting in death (Close et al., 1996, 1997; Makowska et al., 2009). Typically, this is accomplished by blocking interactions of specialized brain regions or decreasing the activity patterns in the brain, with an overall decrease of input to the cerebral cortex and depression of the cardiovascular and respiratory system (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010). Supplying an overdose of an anesthetic agent is generally effective, if the anesthetic is appropriate for that species; however, the time to death can be lengthy and supplemental oxygen should be provided (Canadian Council On Animal Care in Science, 2010; Close et al., 1996, 1997). There are numerous gases that can be used for anesthesia; currently only isoflurane, enflurane, sevoflurane, and desflurane are clinical available in the United States, but clinicians may be able to obtain halothane and methoxyflurane form other suppliers. Isoflurane may artificially elevate blood glucose levels. Enflurane and sevoflurane cause electrocortical activity, behaviorally resulting in convulsions under anesthesia. The order of preference outlined in the *AVMA Guidelines for the Euthanasia of Animals: 2013 Edition* are: isoflurane, halothane, sevoflurane, enflurane, methoxyflurane, and desflurane, with or without nitrous oxide (ether is not acceptable) (American Veterinary Medical Association, 2013).

Injected Agents

Injectable agents delivered parenterally are generally the most rapid, reliable, and preferred method of euthanasia for most species. However, it is important to remember they typically require more handling and restraint, which may be a stressful event for the animal and pose an occupational hazard for the individuals(s) involved (American Veterinary Medical Association, 2013). Intravenous administration is the preferred route for most injectable agents, but in small or debilitated animals, where vascular access can be difficult, other routes can be considered but may have drawbacks (Canadian Council On Animal Care in Science, 2010; Close et al., 1996, 1997; United Kingdom House of Commons, 1986). As a rule of thumb, three to four times the therapeutic dose of an anesthetic will produce rapid and uniform cardiac arrest and death (Close et al., 1996, 1997).

Barbiturate (Pentobarbital)

Barbiturates are the most widely used and accepted agent for euthanasia, reliably resulting in a smooth, rapid euthanasia. Sodium pentobarbital is generally the most suitable, but this group also includes barbituric acid derivatives, oxybarbiturates (sodium pentobarbitone, secobarbital), thiobarbiturates (thiopentone), and barbiturate mixtures (American Veterinary Medical Association, 2013; Close et al., 1996, 1997). Barbiturates cause severe depression of the central nervous system. They interfere with sodium and potassium transport across cell membranes leading to inhibition of the mesencephalic reticular activation system, blocking postsynaptic transmission in all areas of the central nervous system. In addition, they act as positive allosteric modulators and at high doses they bind directly to the γ-amiobutyric acid (GABA) A receptor activating it. This induces a dose-dependent rapid sedation, hypnosis, anesthesia, and eventually respiratory depression and death (Clark et al., 2012; Close et al., 1996, 1997; Perrin, 2015).

Postmortem barbiturate overdose may produce blood parameter changes and pathological artifact both systemically and locally, including congestion, edema, hemorrhage, hemolysis, emphysema, and necrosis (Artwohl et al., 2006; Grieves et al., 2008).

Proper disposal of both the agent, as a controlled substance, and carcass, to avoid poisoning of scavenging wildlife, is important (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010). The advantages of its use, for most species, far outweigh the disadvantages. In addition, there are many pentobarbital combination agents available that include a mixture of a barbiturate and a local anesthetic, other central nervous system depressant, or agents that enhance the metabolism of the barbiturate. This increases the toxicity, but the agents are specifically made for euthanasia and have no therapeutic use (American Veterinary Medical Association, 2013).

Tributame

Tributame is a nonbarbiturate euthanasia agent that contains embutramide, chloroquine phosphate, and lidocaine, which is FDA approved for euthanasia in dogs. Embutramide, a derivative of γ-hydroxybutyrate, is an anesthetic with no therapeutic value due to its severe cardiovascular effects, which include hypotension, myocardial depression, and ventricular dysrhythmias resulting in death. Chloroquine phosphate, an antimalarial drug, was added to shorten the time to unconsciousness and death as it is a profound cardiovascular depressant. The local anesthetic lidocaine was added to reduce the pain associated with intravenous injection in cats. Death occurs as a result of central nervous system depression, respiratory depression and hypoxia, and circulatory collapse. It should only be administered intravenously and caution should be taken if chosen as a euthanasia agent for cats as agonal breathing may occur (American Veterinary Medical Association, 2013).

T-61 (Embutramide, Mebozonium Iodine, and Tetracaine Hydrochloride)

T-61 (Tanax®) is a nonbarbiturate, nonnarcotic mixture of embutramide, mebozonium (mebezonium) iodine, and tetracaine hydrochloride. Embutramide is a general anesthetic that has a strong narcotic effect and acts by causing respiratory depression in the central nervous system and induces deep anesthesia. Mebenzonium iodide is a nondepolarizing neuromuscular blocking agent that paralyzes the skeletal muscle and rapidly induces respiratory collapse. Lastly, T-61 contains the powerful, local anesthetic, tetracaine hydrochloride, which reduces pain at the injection site (American Veterinary Medical Association, 2013; Giorgi and Bertini, 2000; Hellebrekers et al., 1990; Raghav et al., 2011). It is recommended that animal are sedated prior to administration and that it is given slowly, intravenously. It has been described as a euthanasia agent for dogs, amphibians (dorsal lymph sac), small birds (intramuscular), and mammals (intravenous) (Close et al., 1996, 1997). In general, it has a similar induction of euthanasia as pentobarbital; however, you may not see the terminal gasp that sometimes accompanies barbiturate overdose. However, convulsions in birds have been reported (Giorgi and Bertini, 2000; Hellebrekers et al., 1990). There has been concern that an animal might experience paralysis of the diaphragm prior to loss of consciousness, but this has been unfounded with a study showing that loss of consciousness and loss of muscular activity occur simultaneously in dogs and rabbits (Hellebrekers et al., 1990). Postmortem tissue lesions, including endothelial necrosis, hemolysis, pulmonary congestion, and edema, have been described (Giorgi and Bertini, 2000; Raghav et al., 2011). T-61 is no longer marked in the United States but may be available elsewhere (American Veterinary Medical Association, 2013).

Other Injectable Anesthetics and Sedatives

Etorphine hydrochloride and carfentanil citrate are ultrapotent opioids that act on the μ opioid receptors to cause profound CNS and respiratory depression, which leads to death. They are FDA approved for wildlife or exotic animal immobilization and at high enough doses can be used for euthanasia. Caution should be used given the human risk of handling the drug (American Veterinary Medical Association, 2013). Although it is generally not recommend administering euthanasia agents orally due to their prolonged onset of action, inaccurate dosing, and possibility of tissue irritation, carfentanil citrate is absorbed transmucosally and has been proposed as a euthanasia method for great apes when delivered in lollipops (Close et al., 1996, 1997; Kearns et al., 1999, 2000).

The combination of a dissociative agent and an α-adrenergic receptor agonist has been used successfully for euthanasia. The most common duo used in laboratory rodents is an overdose of ketamine (a dissociative agent and NMDA-receptor antagonist) and xylazine (α-adrenergic receptor agonist). Together they induce rapid loss of consciousness and death. The preferred route of administration is intravascular; however, it can be given intraperitoneal, intramuscular, or retroorbital (American Veterinary Medical Association, 2013; Schoell et al., 2009). Given the small muscle mass in mice, intramuscular is not recommended. In addition, an overdose of the injectable hypnotic agent, propofol, may be considered for euthanasia if deemed acceptable for the species and environment (American Veterinary Medical Association, 2013).

Potassium Chloride

Potassium chloride is a cardiotoxin, which at high levels delays electrical conduction between myocytes, resulting in sinoatrial and atrioventricular block, and thus cessation in ventricular conduction. This leads to ventricular fibrillation and fatal asystole. The induced cardiac arrest can generate convulsive seizures, muscle spasms, gasping, and vocalization (Close et al., 1996, 1997; Raghav et al. 2011). Given that the mechanism of action is induction of cardiac arrest without prior unconsciousness, potassium chloride can only be used after the animal is under an surgical plane of anesthesia or rendered unconscious (American Veterinary Medical Association, 2013).

Immersion Agents

General

Immersion methods of euthanasia are generally recommended for aquatic species (e.g., amphibians and fish). Depending on the species it may be absorbed through the gills, ingested, and/or through the skin. It is important that introduction into the dissolved euthanasia agent does not induce pain or distress, thus the pH, temperature, and irritating potential of the solution should be considered. In addition, the water quality, especially temperature, may alter the efficacy of the drug and induction of euthanasia (American Veterinary Medical Association, 2013; Close et al., 1996, 1997). Given that aquatic animals generally have slow metabolic rates and it can be difficult to determine cessation of vital signs, a definitive secondary physical or chemical method is recommended to ensure nonrevival (Canadian Council On Animal Care in Science, 2010). Of note, the *AVMA Guidelines for the Euthanasia of Animals: 2013 Edition* describes immersion in CO_2-saturated water as an acceptable method of euthanasia; however, the Canadian Council on Animal Care guidelines does not find it acceptable and there have been other reports that it does not meet definition of euthanasia, thus it should be used only with great consideration (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010; Matthews and Varga, 2012; Neiffer and Stamper, 2009).

Tricaine Methane Sulfonate (MS-222)

Tricaine methane sulfonate, also known as MS-222, is a benzoic acid derivative commonly used as an anesthetic and euthanasia agent in fish and amphibians. It causes direct depression of the central nervous system by altering the properties of voltage-gated sodium channels, thus blocking the generation of action potentials. At doses five to ten times the anesthetic dose it results in depression of the respiratory system, and accumulation in the myocardium results in decreased cardiovascular function, ultimately resulting in death (American Veterinary Medical Association, 2013; Neiffer and Stamper, 2009; Torreilles et al., 2009). Soluble in both salt and fresh water, the MS-222 must be buffered with sodium bicarbonate prior to placement of the animal in the solution to reduce irritation and skin damage. Like most immersion agents, its efficacy is dependent on the species, animal size, and water quality. For example, an increase in water temperature increases potency (Close et al., 1996, 1997). The solution can be poured over the gills of fish that are too large to immerse (Neiffer and Stamper, 2009).

Benzocaine Hydrochloride

Used as a euthanasia agent in finfish and amphibians, benzocaine hydrochloride has a similar mechanism of action to MS-222. It blocks voltage-sensitive sodium channels within the central nervous system, resulting in depression of the nervous, respiratory, and cardiovascular system, eventually resulting in death (American Veterinary Medical Association, 2013; Torreilles et al., 2009). Benzocaine hydrochloride is not water soluble and must be dissolved in acetone before adding to water. In solution, it will decrease the pH of the tank and caution should be taken to ensure the water is not too acidic before immersing the animal.

2-Phenoxyethanol

Immersion in 2-phenoxyethanol is considered acceptable for the euthanasia of finfish. The mechanism of action is poorly understood but is thought to be secondary to central nervous system depression. Some species variation may be seen with regard to dose and time to loss of consciousness. In addition, some species may show hyperactivity prior to unconsciousness (American Veterinary Medical Association, 2013).

Quinaldine Sulfate

Quinaldine sulfate is a one-step, immersion euthanasia method for finfish. It accumulates in lipid tissue and causes depression of the sensory centers of the central nervous system. The dose to achieve euthanasia is dependent on species, and water quality (i.e., temperature, pH, and mineral content) and induction may be prolonged. It is not water soluble and must be dissolved in acetone prior to making a tank solution (American Veterinary Medical Association, 2013; Close et al., 1996, 1997).

Other Anesthetic Solutions

In general, an overdose of an anesthetic solution will result in death. Cloves contain essential oils (e.g., isoeugenol, eugenol, and methyleugenol) and when used at high concentrations rapidly cause ventricular failure in finfish. Again, the mechanism of action is poorly understood but, similar to other immersion anesthetic agents, it likely inhibits voltage-sensitive sodium channels within the central nervous system (American Veterinary Medical Association, 2013). Inhalant anesthetics (halothane, isoflurane, servoflurane, CO_2) can be bubbled through the tank; however, given the wide range of species variation, this should be considered on an individual basis (American Veterinary Medical Association, 2013; Canadian Council On Animal Care in Science, 2010; Close et al., 1996, 1997).

Miscellaneous Considerations

Topical Benzocaine Gel

Like oral administration, topical absorption of a euthanasia agent is generally slow and efficacy is variable, thus in general this route is generally unacceptable. However, it can be used successfully in animals with highly permeable skin (i.e., amphibians). Benzocaine gel can be placed on the skin of amphibians (American Veterinary Medical Association, 2013; Torreilles et al., 2009).

Sodium Hypochlorite

Sodium hypochlorite (bleach) can be used to euthanize zebrafish up to 7 days postfertilization, prior to nociception. It causes saponification of fatty acids, denatures proteins, and induces derangement of the cellular process ceasing development (American Veterinary Medical Association, 2013).

Invertebrates

Until this paragraph, this chapter has focused on agents used to euthanasia vertebrate animals. However, more information is becoming available on appropriate agents for the euthanasia of invertebrates. The *AVMA Guidelines for the Euthanasia of Animals*: *2013 Edition*, mentions the use of alcohol or formaldehyde in anesthetized aquatic invertebrates, immersion in anesthetic solutions (i.e., magnesium salts, clove oil, eugenol) for aquatic invertebrates, and inhaled anesthetic overdoses or injectable agents for terrestrial invertebrates (American Veterinary Medical Association, 2013).

Anticonvulsant Drugs

Mark G. Papich

Introduction

Treatment of seizure disorders first requires that an accurate diagnosis is made and underlying problems ruled out, such as metabolic disorders, neoplasia, congenital disorders, and intoxication. If a diagnosis of idiopathic epilepsy is made, treatment is usually initiated with one of the maintenance anticonvulsants described in this chapter. Fortunately, excellent current guidelines are available from experts that help guide drug selection (Podell et al., 2016; Bhatti et al., 2015). An evidence-based analysis of anticonvulsant studies in animals provides veterinarians information to make decisions about selection of drugs (Charalambous et al., 2014). Occasionally, animals are presented to veterinary hospitals with continuous seizures – status epilepticus. These animals require prompt treatment with one of the rapidly acting anticonvulsants.

The methods used to classify and diagnosis seizure disorders will not be discussed in this chapter. One should rely on a reputable internal medicine textbook, review paper, or reference that specifically addresses seizure disorders in animals (e.g., Podell, 2013; Muñana, 2013).

In recent Task Force and specialty Consensus Statement Reports (Podell et al., 2016; Bhatti et al., 2015) these drugs are referred to as *antiepileptic drugs* (AED). Here, we will use the term anticonvulsant drugs, which for the purpose of this chapter will be considered interchangeable terms. Anticonvulsant drugs act to limit either the initialization or spread of the seizure focus in the central nervous system. These drugs act to suppress nerve conduction, stabilize neurons, or enhance and potentiate the action of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). For a few drugs, the exact mechanism of action is still unknown. Some drugs, such as the barbiturates, are used for other indications as well. Some barbiturates are better at providing an anticonvulsant effect, and others are better at producing anesthesia. An anticonvulsant is distinguished from an anesthetic by an action that suppresses seizure activity, without producing unconsciousness. Table 17.1 lists anticonvulsant drugs used in veterinary medicine. Some are no longer in use, or are rarely used.

The application of pharmacokinetic principles to treatment of epilepsy in animals has been a major contribution to veterinary neurology. Therefore, the focus of many research publications has been on the pharmacokinetics of the anticonvulsant medications. The pharmacokinetics of several anticonvulsants in dogs, with comparison to humans, was reported by Frey and Löscher (1985), and other papers over the years have followed this pattern with the intent of examining the pharmacokinetics of human-labeled drugs in animals for the purpose of evaluating their potential for veterinary anticonvulsant use. Other relevant papers will be discussed in this chapter among individual drugs. In the paper by Frey and Löscher (1985), they reported significant differences for some drugs, with generally much more rapid clearance in dogs than humans. Protein binding was generally similar for drugs in dogs and people, with the exception of valproate and phenytoin.

The most recent consensus papers and task force reports by experts on this topic (Podell et al., 2016; Potschka et al., 2015; Bhatti et al., 2015) have helped tremendously to guide veterinarians on the best drugs to consider for initial use, the dosages, adverse effects, and evidence to support the clinical use. Drugs most often listed in these guidelines for seizure management include: phenobarbital, bromide, primidone, imepitoin, levetiracetam, and zonisamide. Imepitoin is not approved in the United States, but is available in other countries.

Phenobarbital

Phenobarbital is the most widely used anticonvulsant drug in small animals. Although it is classified as a barbiturate (Figure 17.1) and shares properties with barbiturates discussed in Chapter 12, phenobarbital is unique in its ability to produce an anticonvulsant effect at doses below those that produce anesthesia.

Table 17.1 Anticonvulsants that have been used in veterinary medicine

Barbiturates	Phenobarbital Mephobarbital Primidone
Hydantoins	Phenytoin
Succinimides	Ethosuximide
Benzodiazepines	Diazepam Clonazepam Oxazepam Midazolam Lorazepam
Oxazoldinediones	Trimethadione Paramethadione
Others	Imepitoin Valproate Carbamazepine Potassium bromide Levetiracetam Gabapentin Pregabalin Zonisamide

Mechanism of Action

Phenobarbital increases the seizure threshold and decreases the electrical activity of the seizure focus by potentiating the action of the neurotransmitter GABA. Potentiating the $GABA_A$ subunit increases chloride conductance in neurons, stabilizes electrical activity, and raises the potential necessary for depolarization. Barbiturates also decrease the influx of calcium into nerve cells and thereby decrease release of neurotransmitters. This property may be more important at high phenobarbital levels than at the concentrations that produce an anticonvulsant effect.

Pharmacokinetics

The pharmacokinetics of phenobarbital have been studied in a variety of animals (Frey and Löscher, 1985). Protein binding in serum is 24–30% in sheep, 34–52% in goats, 31% in horses, 19–28% in rabbits, 10–25% in pigs, and 4–23% in cows (Bailey, 1992). This compares with a value of 30–38% in humans.

Phenobarbital is well absorbed with systemic availability that is almost complete in monogastric animals (Pedersoli et al., 1987). The volume of distribution is large and is similar to total body water at 600–700 ml/kg. The high lipophilicity produces penetration across lipid membranes, including the blood–brain barrier of the central nervous system (CNS). Phenobarbital clearance is low in dogs (0.09–0.1 ml/kg/min) (Pedersoli et al., 1987), but it is highly metabolized and relies on hepatic cytochrome P450 enzymes for biotransformation. In people the half-life is in the range of 70–100 hours. In dogs the range has been from 37 to 75 hours (average 53 hours) (Ravis et al., 1984), 89 ± 20 hours (Ravis et al., 1989), and 92.6 (± 24) hours (Pedersoli et al., 1987). In a study that examined variations during the dosing interval in epileptics, the range in half-life among dogs was 20–140 hours, with a mean of 65 hours

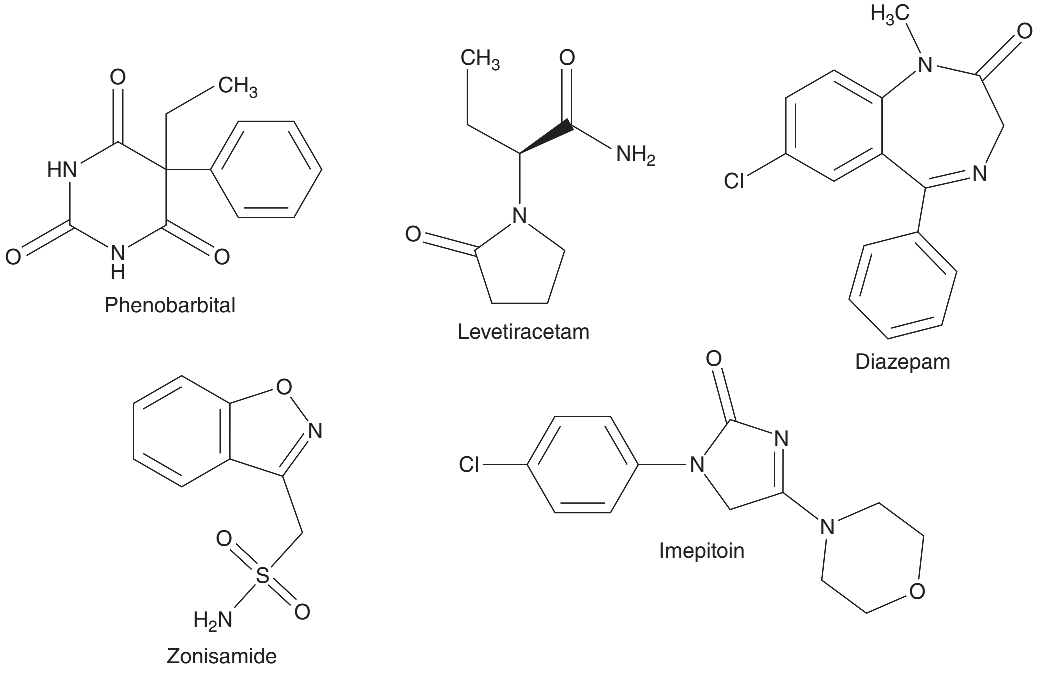

Figure 17.1 Structure of common anticonvulsant drugs used in veterinary medicine.

(Levitski and Trepanier, 2000). As demonstrated from these studies, the half-lives can vary considerably among animals, which may explain a range of plasma concentrations despite similar doses among dogs. This degree of variability supports individualized dosing based on therapeutic drug monitoring. Changes in half-life and clearance that occur during multiple dosing is caused by autoinduction of hepatic metabolism (Ravis et al., 1989; Hojo et al., 2002), and may also be influenced by diet (Maguire et al., 2000). With multiple dosing, the half-life decreased from 89 hours (± 19.6) on day 1 to 47 hours (± 11) at day 90. After multiple dosings produce autoinduction of hepatic enzymes, clearance almost doubled in dogs (Ravis et al., 1989). After multiple oral treatments with phenobarbital, the liver cytochrome P450 content was twofold higher and plasma concentrations lower, compared to untreated dogs (Hojo et al., 2002). The activity of CYP1A, 2C, and 3A were increased by two- to fourfold compared to untreated dogs.

In cats the half-life ranges from 35 to 56 hours (average 43 hours) and from 59 to 76 hours, depending on the study (Cochrane et al., 1990a, 1990b). In horses the half-life is approximately 18–19 hours; however, one study showed a half-life of 24 hours after a single dose but 11.2 hours after multiple doses (Knox et al., 1992; Duran et al., 1987; Ravis et al., 1987). In foals the mean half-life was 13 hours (Spehar et al., 1984). These values for horses indicate a more rapid clearance in horses than in other species. In birds the half-life is short, which makes it difficult to maintain effective concentrations. Despite high doses in parrots, the half-life was only 1.4–1.7 hours, with low peak concentrations (Powers and Papich, 2011).

Drug Interactions

Phenobarbital is a well-known inducer of microsomal cytochrome P450 (CYP450) enzymes (microsomal enzymes) that metabolize drugs (Hojo et al., 2002). Phenobarbital is an inducer of canine CYP2B11, CYP3A12, CYP2C21/2C41, and possibly others (Martinez et al., 2013). Increased amounts of CYP450 enzymes have been documented and are found in the endoplasmic reticulum of hepatocytes.

Induction of microsomal enzymes may cause enhanced biotransformation of other drugs, which can diminish the pharmacological effect for a drug that is administered concurrently (e.g., digoxin, corticosteroids, phenylbutazone, some anesthetics, and antipyrine). When phenobarbital was administered with another anticonvulsant to dogs, levetiracetam, the clearance and half-life of levetiracetam was significantly altered, producing a shorter half-life and faster clearance in dogs (Moore et al., 2011). The authors of the study concluded that concurrent phenobarbital administration significantly alters the pharmacokinetics of levetiracetam in dogs, indicating that dosage adjustments might be necessary when the drug is administered with phenobarbital. Phenobarbital will also increase the clearance of zonisamide by at least 50%, requiring an adjustment of the dose of zonisamide if it is administered with phenobarbital (Orito et al., 2008). (Zonisamide and levetiracetam are discussed later in this chapter.) It was also observed that if a canine patient has been receiving maintenance therapy with phenobarbital, the concentration of diazepam and metabolites were lower after intravenous and rectal administration compared to diazepam administration prior to phenobarbital treatment. Therefore, it may require higher doses of diazepam in some dogs to control periodic seizures because of increased clearance caused by enzyme induction (Wagner et al., 1998). Enzyme induction will also increase phenobarbital's own metabolism. In one study (Maguire et al., 2000), the half-life at the beginning of the study was 47–49 hours in dogs. But, after chronic treatment for 2 months, the phenobarbital half-life decreased to 24–33 hours. In another study, autoinduction of enzymes significantly lowered the phenobarbital plasma drug concentration in dogs compared to the expected level that would ordinarily occur from multiple dosing (Hojo et al., 2002).

Other drugs that are microsomal enzyme inhibitors (CYP450 inhibitors) may inhibit the metabolism of phenobarbital and cause toxicity if the two drugs are administered concurrently. Chloramphenicol and ketoconazole are examples of these CYP450 enzyme inhibitors (Martinez et al., 2013).

Side Effects, Adverse Effects, and Tolerance

Side effects that one may expect include sedation, polyphagia (with associated weight gain), polyuria/ polydipsia, and mild behavior changes. These may subside somewhat after the first few weeks of treatment because both pharmacokinetic and pharmacodynamic tolerance develops with chronic therapy. Pharmacokinetic tolerance is caused by enhanced metabolism owing to induction of the hepatic enzymes (i.e., phenobarbital increases its own metabolism) with chronic dosing that was discussed above. Pharmacodynamic tolerance is determined by the sensitivity of receptors.

Liver: Elevated hepatic enzymes have been observed after chronic therapy in healthy animals (ALT, alanine aminotransferase; ALP, alkaline phosphatase) without an association with hepatic injury (Aitken et al., 2003; Gieger et al., 2000; Müller et al., 2000a; Chauvet et al., 1995). The highest elevations occur with serum ALP. Elevations in hepatic enzymes that are not associated with liver pathology are reported to be caused by induction of the enzymes by the drug and are expected to return to normal 3–5 weeks after the drug is discontinued (Gieger et al., 2000). In one study of 95 epileptic dogs controlled with phenobarbital, the increases in liver enzymes were related to the phenobarbital plasma concentration (Aitken et al., 2003). Dogs with the highest levels of phenobarbital also had the highest ALT increases.

Hepatotoxicosis also is possible from phenobarbital. It has been described as both an intrinsic and idiosyncratic hepatic injury. In clinical reports, most affected dogs had high serum phenobarbital concentrations (>40 μg/ml) (Dayrell-Hart et al., 1991). Animals with phenobarbital-induced hepatotoxicosis had bilirubin increases that were disproportionately elevated in comparison to the ALP. There also may be elevations in bile acids or other signs of hepatic disease. Liver lesions include chronic fibrosis with nodular regeneration, biliary hyperplasia, necrosis, and cirrhosis (March et al., 2004). Animals receiving high doses of phenobarbital to control seizures should be examined periodically because they may be at a higher risk of developing liver disease. Although hepatic injury has been an important concern associated with administration of phenobarbital to dogs, this has not been a documented problem in cats.

Hepatocutaneous disease: As a consequence of phenobarbital-induced liver disease, the skin also may be affected. This has been described as *superficial necrolytic dermatitis,* more commonly known as *hepatocutaneous syndrome*. The hepatocutaneous syndrome has been associated with phenobarbital administration in some dogs (March et al., 2004). Prolonged phenobarbital exposure and high plasma drug levels may contribute to this disease in dogs.

Blood disorders: Anemia, thrombocytopenia, and neutropenia have been described as a result of phenobarbital administration (Jacobs et al., 1998). It is rare, and probably idiosyncratic, but should be considered in a patient that shows signs of a blood disorder in association with phenobarbital treatment.

Effect on hormones: Phenobarbital administration may alter thyroid hormone levels (Gieger et al., 2000; Kantrowitz et al., 1999). After multiple doses, it may decrease thyroxine (T_4) and free T_4 in dogs, but not T_3 (Kantrowitz et al., 1999). In one study, T_3 was increased slightly (Müller et al., 2000b). Thyroid stimulating hormone (TSH) has been mildly elevated in some studies, but not others (Müller et al., 2000b; Gieger et al., 2000). Thyroid hormones and TSH return to normal within 4 weeks after discontinuing phenobarbital treatment. The mechanism for the effect on thyroid hormone is probably via an increase in T_4 metabolism induced by phenobarbital (Kantrowitz et al., 1999; Gieger et al., 2000).

Corticosteroid metabolism: In experimental animals and humans phenobarbital accelerates steroid metabolism. This may decrease the therapeutic effects of corticosteroid administration. However, there is no evidence that phenobarbital treatment induces adrenal disease in dogs. The effect of phenobarbital administration to dogs on adrenal cortex diagnostic tests has been examined (Dyer et al., 1994; Chauvet et al., 1995). Phenobarbital administration to dogs did not affect response to exogenous adrenocorticotropic hormone (ACTH) or the levels of endogenous ACTH.

Clinical Use

Phenobarbital is considered the first drug of choice for long-term treatment of seizure disorders in dogs and cats (Podell et al., 2016). Its efficacy has been estimated to be approximately 60–90%. It also has been used to treat some behavior disorders in dogs and cats. Daily dosages of 4–16 mg/kg/day have been used, but dogs are usually started on 2.5–3 mg/kg q 12 h and adjusted up to 6–8 mg/kg q 12 h, gradually – if necessary. Even though the half-life is long in dogs, most animals are initially treated with phenobarbital on an every-12-hour schedule to decrease side effects and ensure minimal peak–trough fluctuations. In some patients, however, once-a-day dosing may be effective.

The typical starting dose for cats is 1.5–2.5 mg/kg, q 12 h, PO (Quesnel et al., 1997; Platt, 2001; Finnerty et al., 2014). In some cats, doses are increased to 2–4 mg/kg, q 12 h, PO. A common dose in cats is 7.5 mg per cat, q 12 h (half of a 15-mg tablet), and the dose may be adjusted by 7.5-mg increments.

In horses, the initial doses are 11 mg/kg q 24 h. When chronic therapy has been needed the dose may be increased to 25 mg/kg q 24 hr.

Treatment of status epilepticus: Phenobarbital may be injected in animals for the treatment of status epilepticus. One of the consensus documents (Bhatti et al., 2015) recommends a loading dose of 15–20 mg/kg IV, or IM, followed by additional doses in increments of 3–5 mg/kg over 24–48 hours until seizure control is maintained, or therapeutic plasma/serum concentrations are attained. One author recommends that in naïve animals (not previously on anticonvulsant maintenance medication), a loading dose of 12 mg/kg IV should be used, followed by 2–4 mg/kg increments every 20–30 minutes until seizure control is achieved (Muñana, 2013). Phenobarbital infusions also have been administered at the rate of 3–6 mg/dog per hour, IV (Bateman and Parent, 2000). Phenobarbital does not cross the blood–brain barrier as fast as diazepam; therefore, it may take several minutes for an anticonvulsant effect to treat status epilepticus. In severe cases, pentobarbital has been administered to effect, starting with doses of 4–20 mg/kg IV. Pentobarbital is not a good anticonvulsant; its use in this instance is simply to anesthetize the patient until additional therapy can be provided.

Formulations: Typically, phenobarbital tablets are the preferred dose formulation. There is also an injection formulation for IV use, and a liquid elixir. Because the elixir is bitter for many animals, phenobarbital occasionally has been compounded into an oral liquid for administration to small dogs and cats. These compounded formulations have been stable for 115 days.

Because cats may be difficult to medicate orally, a compounded transdermal formulation has been prepared in a polymer gel or proprietary compounding base to enhance absorption across the skin and applied to the ears of cats (Gasper et al., 2015; Krull et al., 2014). However, in one study the formulation in a pluronic lecithin organogel (PLO) matrix had inconsistent and low potency and at a dose of 6 mg/kg twice daily produced measurable, but subtherapeutic, plasma concentrations in cats (Krull et al., 2014). Another study using a compounded transdermal formulation showed that effective concentrations can be achieved in cats if a high dose of 9 mg/kg every 12 hours was administered (Gasper et al., 2015).There are no commercial forms available for transdermal application. Consistency of the formulations and long-term safety have not been evaluated.

Clinical Monitoring

To adjust dose, monitor compliance, and assess toxicity it is the usual practice to monitor plasma or serum phenobarbital concentrations regularly during therapy. Assays are available at most diagnostic laboratories. This can be done initially after the first 2 weeks of starting treatment and then every 6–12 months, or as needed to assess treatment. The recommended plasma/serum therapeutic concentration for dogs is 15–40 μg/ml (65–180 mmol/l). Some neurologists list this range as 20–45 μg/ml and 15–45 μg/ml, and a consensus panel listed 25–35 μg/ml (Bhatti et al., 2015) and 15–35 μg/ml (Podell et al., 2016) as the effective range. If dogs are also receiving bromide (see Section Bromide (Potassium and Sodium Bromide)), phenobarbital concentrations in the range of 10–36 μg/ml have been reported as therapeutic (Trepanier et al., 1998).

For cats, the plasma concentrations can be variable, but the optimum range has been cited as 23–30 μg/ml (Quesnel et al., 1997). In another study in cats, seizure control was achieved in 93% of cats when concentrations were between 15 and 45 μg/ml (Finnerty et al., 2014). In the cited study by Quesnel et al. (1997), cats were more unstable than dogs, possibly because of more serious CNS disease and required more frequent monitoring.

Because phenobarbital has such a long half-life, fluctuations between plasma peaks and troughs are minimized when it is administered on an every-12-hour schedule. Therefore, the timing of samples usually makes no difference when a sample is collected during a 12-hour schedule for the assessment of plasma phenobarbital concentrations (Levitski and Trepanier, 2000). However, in one study the trough concentrations were lower than at other times during the day when dogs received greater than 10 mg/kg per day, and they recommended always monitoring each individual patient at the same time after dosing to obtain consistent results (Monteiro et al., 2009).

Primidone

Primidone (Mylepsin, Mysoline) is a barbiturate derivative metabolized to phenobarbital and phenylethylmalonamide (PEMA). Primidone and its two major metabolites have anticonvulsant activity but at least 85% of the pharmacological activity is derived from phenobarbital. Primidone has been around for a long time and was once more widely used in dogs (but rarely in cats). But, since the 1980s, there has been little new information generated for primidone and its use has declined.

Pharmacokinetics

In addition to the differences in potency, PEMA and primidone do not persist in the plasma for as long as phenobarbital, which raises questions regarding the activity of PEMA and primidone throughout a long dosing interval (Frey et al., 1979). When primidone was administered to dogs, the half-life (mean value) of PEMA was 7.1 hours, the half-life of primidone was 1.85 hours, and the half-life of phenobarbital was 41 hours (Yeary, 1980). After multiple dosing in this study the primidone concentrations decreased, probably caused by accelerated metabolism.

Clinical Efficacy

Although seizures can be controlled with primidone in dogs (Schwartz-Porsche et al., 1982), primidone has little advantage over phenobarbital. Control of seizures in dogs is correlated with the plasma concentrations of phenobarbital, rather than primidone (Cunningham et al., 1983). In a comparison between primidone and phenobarbital in epileptic dogs (Schwartz-Porsche et al., 1982), there was no significant difference between phenobarbital and primidone with respect to seizure control, and primidone appeared more likely to induce liver injury than phenobarbital. The authors concluded that phenobarbital, rather than primidone, should be the drug of first choice for treatment of canine epilepsy.

However, there may be rare cases that respond to primidone when phenobarbital alone has not been effective (1 out of 15 according to Farnbach, 1984). Primidone is more expensive than phenobarbital, but it is not classified as a controlled drug in the USA; therefore, it is not subject to the same degree of regulation as phenobarbital.

Adverse Effects

Most adverse effects and side effects are the same as those listed for phenobarbital; however, primidone administration may be associated with a higher incidence of hepatotoxicity. Hepatic necrosis, fibrosis, and cirrhosis have been associated with chronic use of primidone (Bunch, 1989). Intrahepatic cholestasis has occurred in dogs in which primidone was combined with phenytoin.

Manufacturers do not recommend its use in cats; in fact, it is stated on the package insert that its use should be cautioned in cats. However, studies in cats have demonstrated that primidone is probably safe.

Clinical Use

Initial dosages in dogs are 3–5 mg/kg q 8–12 h, but have been increased up to 12 mg/kg q 8 h. If one is converting a patient from primidone to phenobarbital or vice versa, the conversion is the following: 65 mg phenobarbital = 250 mg primidone.

Therapeutic Monitoring

The effects of primidone are associated with the concentrations of phenobarbital; therefore, clinical monitoring should rely on phenobarbital concentrations (see recommended concentrations listed in Section Phenobarbital, Clinical Monitoring). Measurements of PEMA or primidone are not available in most laboratories.

Phenytoin

Phenytoin (Dilantin, formerly diphenylhydantoin) is one of the most commonly prescribed anticonvulsants in human medicine. In veterinary medicine, its use is rare because of pharmacokinetic differences and susceptibility to adverse effects. It is *not* a recommended anticonvulsant for dogs or cats. It is used occasionally in horses for muscle disorders or as an antiarrhythmic agent.

Mechanism of Action

Phenytoin stabilizes neuronal membranes and limits the spread of neuronal or seizure activity from the focus. It blocks inward movement of Na^+ and stabilizes excitable tissue (this drug is also used as a Class I antiarrhythmic agent, see Chapter 22). Phenytoin also decreases Ca^{+2} inward flow during depolarization, thus, inhibiting Ca^{+2}-dependent release of neurotransmitters (presynaptic).

Pharmacokinetics

There are important interspecies differences among animals and between animals and humans that cause difficulty in maintaining effective concentrations. Phenytoin is eliminated much more rapidly in dogs than in people (Frey and Löscher, 1985). Because of its rapid elimination, phenytoin is not recommended as an anticonvulsant in small animals. In cats, the elimination is very slow, and toxicity has been a concern. In horses the pharmacokinetics have been described (Soma et al., 2001), but are highly variable among horses. The half-life was approximately 12–13 hours, depending on the route of administration, but the oral absorption ranged from 14 to 85% among horses.

Clinical Use

Phenytoin is available in 25 mg/ml oral suspension; 30 and 100-mg capsules (sodium salt); and 50 mg/ml injection (sodium salt). For dogs, these formulation sizes result in an impractical dose (several capsules per day) for a large-size dog. Nevertheless, a dose recommended for dogs is 20–35 mg/kg q 8 h and the antiarrhythmic dose is 30 mg/kg q 8 h PO or 10 mg/kg IV over 5 minutes. It should not be used in cats.

Horses: Phenytoin has been used in horses for tying-up syndrome. This is a use primarily employed on the racetrack in athletic horses. The use is not related to the anticonvulsant property. In horses, at high doses recumbency and excitement have been observed. Sedation in horses may be an initial sign of high plasma phenytoin concentrations. Phenytoin pharmacokinetics are highly variable in horses, particularly the extent of absorption (Soma et al., 2001). Because of this variability it is difficult to maintain consistent plasma concentrations. Monitoring plasma concentrations may be necessary to adjust the dose to maintain an optimum level and prevent adverse effects. Suggested doses for horses are to administer an initial bolus of 20 mg/kg q 12 h PO, for four doses, followed by 10–15 mg/kg q 12 h PO. A single IV dose in horses of 7.5–8.8 mg/kg can be used, followed by oral maintenance doses.

Therapeutic Monitoring

Therapeutic drug monitoring can be performed; however, therapeutic concentrations have not been established for dogs and cats. Effective plasma concentrations listed for people are between 5 and 20 μg/ml. In the absence of other data, an average peak concentration of 15 μg/ml has been used as a target for animals. In horses, effective plasma concentrations are 5–20 μg/ml (average 8.8 μg/ml ± 2 μg/ml) (Soma et al., 2001). Therapy should be aimed at producing concentrations above 5 μg/ml in horses, or a peak concentration of 15 μg/ml.

Valproic Acid (Valproate)

Valproic acid (Depakene®) has been used in dogs primarily when they are refractory to other medications. The use has declined after other drugs became available (see Sections Zonisamide, Gabapentin, and Levetiracetam), but it has been used in some dogs successfully. The mechanism of action is unknown. It may interfere with GABA metabolism.

Pharmacokinetics

Absorption from oral valproate is high in dogs, with values for the immediate-release tablets of 100% (Bialer et al., 1984) and sustained-release preparations of approximately 80%. The half-life in dogs is 1.0–2.8 hours (15–20 hours in people), or approximately 1.4 hours in another study in dogs (Bialer et al., 1984). This short half-life severely limits its therapeutic effectiveness unless frequent dosing schedules are used or sustained-release products are employed. But, some evidence suggests that the anticonvulsant effects of valproate persist long after the drug is eliminated from the plasma.

Clinical Use

According to some studies in dogs (Bialer et al., 1984; Bialer, 1992), the sustained-release tablets provide a more sustained plasma concentration than conventional tablets. However, half-life and extent of absorption may be different between valproate pharmacokinetics in dogs and humans; therefore, the human extended-release dosage forms may be applied to dogs, but should be administered more frequently than in humans (Bialer, 1992; Bialer et al., 1986).

Divalproex sodium is composed of equal parts of valproic acid and valproate. It is pharmacologically equivalent to valproic acid and is available in delayed-release tablets of 125 and 500 mg (Depakote®, Epival®).

Although valproate is not commonly used, some neurologists have reported it to be "reasonably effective" and well tolerated. Combining this drug with another anticonvulsant such as phenobarbital may increase its efficacy. Dosages that have been used in dogs range from 75 to 200 mg/kg q 8 h when used alone, or 30 to 40 mg/kg/day with phenobarbital (phenobarbital dose is usually decreased). Drug assays exist for therapeutic monitoring, but this is not commonly performed for animals. The therapeutic concentrations are reported to be 350–830 μmol/ml (50–120 μg/ml), but the true "therapeutic range" for valproate in animals is not known.

Imepitoin

Imepitoin is approved for treating epilepsy in dogs in Europe, but not the USA. In Europe, the brand name is Pexion, it was approved in 2013, and is considered a first-line treatment for idiopathic epilepsy in dogs. Veterinarians in the USA have not been familiar with imepitoin.

The mechanism of action of imepitoin is to decrease seizures by potentiating the $GABA_A$ receptor-mediated inhibitory effects. Although structurally it is not classified as a benzodiazepine, these actions are similar to diazepam and other benzodiazepines (Figure 17.1). The similar action to benzodiazepines is caused by its low-affinity binding for the benzodiazepine binding site of $GABA_{A,}$ but it has 600 times less affinity for the binding site compared to diazepam. It also may have a weak calcium channel blocking effect, which may contribute to clinical effects.

Clinical Use in Dogs

The approved dose for dogs of imepitoin is 10–30 mg/kg oral twice daily. It is available in 100 and 400-mg tablets, which can be split if necessary. It is recommended to start with 10 mg/kg, then increase dose to obtain the desired response. There have been no guidelines thus far for plasma/serum concentration monitoring; therefore, dose adjustment should be made on the basis of clinical response. The dose can be increased by 50 to 100% increments up to a maximum dosage of 30 mg/kg administered twice daily.

In a US field trial it was compared to primidone in dogs. Imepitoin efficacy was lower than primidone, but was judged to be not inferior, and produced fewer adverse effects in dogs compared to primidone. In the field trials that led to the approval for use in Europe, the efficacy of imepitoin was compared to phenobarbital in dogs with idiopathic epilepsy. The European agency concluded that although there was lower overall efficacy for imepitoin compared to phenobarbital, some dogs were well-controlled with imepitoin treatment. They stated that although efficacy may not be complete with imepitoin treatment in dogs, it is considered a “suitable treatment” in some dogs because of its safety profile. The ACVIM consensus panel (Podell et al., 2016) gave it a high rating for use as single-drug monotherapy, but a rating of low as an add-on medication. In the published study in which it was compared with phenobarbital for idiopathic epilepsy in dogs (Tipold et al., 2015), there were significantly fewer adverse events with imepitoin compared to phenobarbital. Although the efficacy was lower for imepitoin than phenobarbital, the analysis showed imepitoin to be statistically noninferior. It has not been evaluated for treatment of status epilepticus. The use as an add-on treatment with other drugs has not been sufficiently tested, except in a pilot study in which there were add-on benefits (Rieck et al., 2006). There have been no studies reported in cats or other animals.

Pharmacokinetics

Studies in dogs indicate that half-life of imepitoin in Beagle dogs was relatively short compared to other anticonvulsant drugs. The half-life was 1.5–2 hours, but it can be administered only twice daily (Rundfeldt and Löscher, 2014). Most of the elimination is by the feces. The authors of the study suggested that it may have shorter half-life in Beagle dogs than other breeds, but those studies may not be representative of clinical patients. Concentration profiles were not much different in fed versus fasted Beagle dogs. The total area-under-the-curve (AUC) was higher in the fasted dogs, even though this may not be enough of a difference to be clinically relevant. The protein binding was 56–57%, but no protein-binding drug interactions have been identified.

Adverse Effects

The most common adverse effects from imepitoin reported in field trials were lethargy/sedation, polyuria/polydipsia, and increased appetite. Most reactions are mild and generally transient. Other reported effects are hyperactivity, hypersalivation, emesis, ataxia, diarrhea, and sensitivity to sound. In the clinical studies it produced fewer adverse effects compared to primidone or phenobarbital. In clinical studies, although phenobarbital was associated with increasing levels of the liver enzymes ALT, ALP, aspartate aminotransferase (AST), γ-glutamyl transferase (GGT), and glutamate dehydrogenase (GLDH), none of these enzymes increased with imepitoin. Although it is a partial agonist for the $\mathrm{GABA_A}$ binding site, there is no evidence of tolerance or dependence that develop from repeated administration of imepitoin.

Drug Interactions

Imepitoin is metabolized by the liver enzymes; therefore, interactions with other drugs that affect cytochrome P450 enzymes are possible, but have not been studied in dogs. It did not affect activity of most human P450 isoforms but inhibition of CYP1A1 is possible (Rundfeldt and Löscher, 2014). Imepitoin had no effect on enzyme induction compared to phenobarbital (Rundfeldt and Löscher, 2014). It is a partial agonist for the benzodiazepine receptor, but there is no evidence that it will prevent the activity of coadministered benzodiazepines used for acute treatment (e.g., status epilepticus). In a pilot study (Rieck et al., 2006), there was no evidence of interaction with coadministered phenobarbital in dogs.

Imepitoin is poorly soluble and dissolves more readily at an acid pH. Therefore it is possible that suppressing acid in the stomach (for example with proton pump inhibitors such as omeprazole) could interfere with oral absorption.

Benzodiazepines

Diazepam

Diazepam belongs to the class of benzodiazepines (Figure 17.1). Diazepam (Valium) is an important drug for treating acute seizures and status epilepticus, but is not practical for long-term therapy. Diazepam along with other benzodiazepines is discussed in Chapters 9, 14, and 18.

Mechanism of Action

The mechanism of action as an anticonvulsant is caused by the action to hyperpolarize neurons and suppresses neuronal activity. Benzodiazepines accomplish this action through interaction with the inhibitory neurotransmitter GABA. The $\mathrm{GABA_A}$ receptor subunit is the most prominent. It is a ligand-gated chloride ion ($\mathrm{Cl^-}$) channel and the site of action of many neuroactive drugs, such as benzodiazepines, barbiturates (discussed previously), and some anesthetics. Benzodiazepines act on $\mathrm{GABA_A}$ by binding to a specific site that is distinct from that of GABA binding. They do not activate GABA receptors directly (which is the action of barbiturates) but modulate the effects of GABA. From the interaction with $\mathrm{GABA_A}$, the frequency of GABA-activated $\mathrm{Cl^-}$ channels is increased.

Pharmacokinetics

In humans the half-life is 43 hours (mean) but may range from 24 to 48 hours, and as high as 60 hours. It has a low hepatic extraction rate compared to dogs. In dogs, the half-life is much shorter (Frey and Löscher, 1985), with a high hepatic extraction rate, which makes this drug unsuitable for most dogs for chronic anticonvulsant therapy. The half-life from IV administration has been reported to be as rapid as 15 minutes and as long as 3.2 hours, depending on the study (Papich and Alcorn, 1995). Diazepam is rapidly converted to two metabolites. It is first demethylated to *N*-desmethyldiazepam (also called nordiazepam), then to oxazepam. The metabolites are eliminated more slowly than diazepam and have equal to one-third the potency of diazepam, depending on the study used to determine potency. The half-life of the desmethyldiazepam metabolite is 2.2–3.6 hours and of oxazepam is 3.83–5.7 hours. In cats, the half-life of diazepam is 5.5 hours, with the half-life of the metabolite 21 hours. Diazepam is highly lipophilic, more so than other drugs in this class. Its high lipophilicity produces high concentrations in the CNS rapidly after IV injection, which is why this drug is so useful in emergency situations to treat status epilepticus.

Clinical Use

Diazepam is usually the first drug of choice for treating status epilepticus because it is distributed rapidly to the CNS after IV administration. But, it is unsuitable for chronic treatment in dogs because frequent administration is required. There are also other disadvantages: tolerance develops with repeated administration, animals may develop dependence, and there is abuse potential (by animal owners).

For emergency use in dogs, diazepam is administered IV at a dose of 5–20 mg/animal (diazepam concentration is 5 mg/ml). The equivalent dose is approximately 0.5 mg/kg. Diazepam is lipophilic (Log P 2.76) and crosses the blood–brain barrier quickly for a rapid effect. It has a short duration of action, but the metabolites (desmethyldiazepam and oxazepam) are active and have longer half-lives. Repeated doses may be administered to patients that continue to seize, but some veterinarians have utilized constant rate infusions. Infusion doses are in the range of 0.5 mg/kg per hour, IV (Bateman and Parent, 2000). One must be aware of the potential for diazepam to adsorb and absorb to plastic IV infusion sets when administered as an IV infusion.

Rectal administration: Rectal administration is a convenient alternative to IV dosing in an animal with status epilepticus when intravenous or oral administration is not practical. Diazepam is rapidly absorbed by this route (Papich and Alcorn, 1995) and has been effective in dogs for at-home treatment of cluster seizures (Podell, 1995). The 5 mg/ml injectable solution has been instilled in the rectum with a syringe starting at a dose of 0.5–1 mg/kg, and as high as 2 mg/kg. The study by Wagner et al., (1998) concluded that 2 mg/kg via the rectal route was appropriate, even if dogs had been receiving chronic phenobarbital. A small plastic teat cannula attached to the end of the syringe has been used to facilitate administration. A formulation in gel has been made available for this use (Dreifuss et al., 1998), but it is more expensive.

Other routes of administration: Other routes have been used, such as intranasal and mucosal (gingival). The only one of these routes that has been examined well in dogs was the nasal route. Intranasal administration of 0.5 mg/kg to Greyhounds produced plasma concentrations of diazepam and metabolites in an effective range for seizure control (Platt et al., 2000). A more detailed study that analyzed specific metabolites showed that after intranasal administration of 0.5 mg/kg to dogs, effective concentrations were reached within 5 minutes (Musulin et al., 2011). Although diazepam had a short half-life of approximately 2 hours in that study, the half-life of the active metabolites (desmethyldiazepam and oxazepam) was much longer. Both these studies conclude that intranasal administration may be an effective method of administration to dogs with status epilepticus.

Diazepam in cats: In cats diazepam has a longer half-life than dogs and has been used as a drug to control seizures, treat behavioral problems, and stimulate appetite (see Chapter 18). In cats, dosages of 0.25–0.5 mg/kg q 8 h, PO are used. This dose may be increased to 1–2 mg/kg q 8 h for seizure control. Adverse hepatic effects (discussed in Section Adverse Reactions and Tolerance) have caused a decline in the long-term administration to cats.

Adverse Reactions and Tolerance

Some neurologists have observed that patients may become refractory to chronic treatment (tachyphylaxis) because there may be a feedback decrease in benzodiazepine receptor synthesis or a decreased synthesis of GABA. Tolerance in dogs may be seen after 1 week of dosing. After long-term administration, withdrawal should be done gradually and carefully because some dependence occurs. Signs of withdrawal may include increased anxiety and tremors.

Hepatic toxicosis in cats: Hepatic necrosis in cats has been reported from oral administration of diazepam (Center et al., 1996). This reaction can be severe and fatal. The liver injury usually appears after the initial 5 days of treatment. Diazepam-induced hepatic injury in cats may be caused by slow metabolism to the metabolite temazepam, and inhibition of the bile salt export pump, causing accumulation of bile acids in hepatocytes (Van Beusekom et al., 2015). Because of this reaction, other benzodiazepines should be considered in cats.

Other Uses

Skeletal muscle relaxant: Benzodiazepines may act as muscle relaxants by inhibiting certain spinal pathways – most likely through GABA effects – or by directly depressing motor nerve and muscle function. Examples of their use have been relaxation of urethral skeletal muscle in cats following obstruction and relaxation of skeletal muscle associated with spinal disk disease. Their clinical efficacy as muscle relaxants has been questioned.

Treatment of anxiety, aggression, and behavioral disorders in small animals: Because benzodiazepines are common drugs in human medicine for emotional disorders – anxiety, stress, phobias, aggression, insomnia, etc. – they have also been administered to dogs and cats for a large variety of disorders with varied success. Other benzodiazepines, such as alprazolam, are usually used for treatment of anxiety disorders in animals. A discussion of the use of alprazolam and other benzodiazepines for behavior problems can be found in a review paper (Simpson and Papich, 2003) and in Chapter 18.

Diazepam-induced eating in anorexic cats: Benzodiazepines stimulate the appetite in anorexic cats (less effective in dogs). Diazepam has been administered for this purpose at dosages of 0.04–0.05 mg/kg, IV. Oral oxazepam also has been used for this indication.

Midazolam

Midazolam does not have a role in chronic management of seizure disorders in animals, but has been used to treat status epilepticus. It is also frequently used as an anesthetic adjunct, which is discussed in Chapter 14. Midazolam acts in the same manner as other benzodiazepines. An important difference between midazolam and diazepam is the solubility. At a pH <4 it exists in an open-ring form allowing preparation of water-soluble salts. It is capable of achieving an equilibrium in this soluble form because the solution (midazolam hydrochloride) has pH of approximately 2.5 to 3.7, adjusted with hydrochloric acid and, if necessary, sodium hydroxide. The aqueous midazolam preparation produces little tissue irritation and can be administered intramuscular or intravenous in aqueous solutions. Following injection, the more neutral pH of the body (pH above 5.5) converts midazolam to a closed-ring form, which facilitates its lipid solubility. It is almost as lipophilic as diazepam at this pH (Log P 2.68) and readily crosses the blood–brain barrier for treatment of status epilepticus.

The pharmacokinetics of midazolam have been studied (Schwartz et al., 2013) with pharmacokinetics of other studies summarized in that report. Because of favorable absorption and ease of administration, midazolam has become a useful emergency treatment for seizures at a dose of 0.2 mg/kg (solution is 5 mg/ml). The systemic availability from an intramuscular (IM) injection in dogs was 50% (Schwartz et al., 2013). However IM absorption was variable among dogs and a dose higher than 0.2 mg/kg should be used to ensure high enough concentrations for treating seizures. Unlike diazepam, absorption following rectal administration of midazolam was low and unlikely to be effective (Schwartz et al., 2013). Intranasal midazolam was absorbed in dogs well enough to produce 70% efficacy within 47 seconds for treating status epilepticus (Charalambous et al., 2017). The half-life in dogs is short (approximately 1 hour) and additional doses may be needed if prolonged seizure control in the hospital is needed.

Clonazepam

Clonazepam (Klonopin) is another benzodiazepine with a mechanism of action similar to diazepam, but it is more potent. There is anecdotal evidence that it is a good anticonvulsant in dogs that are refractory to phenobarbital therapy, but this should be considered only as a last resort. Clonazepam undergoes saturable (zero order) elimination. As the dose is increased, or if animals are dosed for longer than 1 week, the half-life increases (e.g., from 1.5 hours to 3 hours). As for other antiepileptic drugs, the half-life is much longer in humans compared to dogs. The starting dose recommended for dogs is 0.5 mg/kg, two to three times a day (Frey and Löscher, 1985). In cats, clonazepam has been used as an alternative to diazepam to avoid the risk of hepatotoxicity. The starting dose is 0.5 mg/kg once or twice daily in cats.

Withdrawal syndrome is possible from chronic therapy with clonazepam. If dogs are receiving clonazepam and there is abrupt cessation of therapy, signs of acute withdrawal can be seen, which include listlessness, weight loss, pyrexia, and recumbency. Cessation of this drug should be tapered over a period of 1 month to minimize these effects.

Clorazepate

Clorazepate (Traxene) is another benzodiazepine that has also been considered for treating seizures in animals. But because of lack of published data on efficacy and availability of other choices, clorazepate should be considered only after other treatments have been attempted. Although there is no published information regarding its efficacy in dogs, anecdotal reports indicate that it may be effective in some refractory cases.

Clorazepate is hydrolyzed to desmethyldiazepam (nordiazepam), an active metabolite of diazepam. The half-life of desmethyldiazepam is 3–6 hours in dogs (30–100 hours in man) (Frey and Löscher, 1985; Papich and Alcorn, 1995; Musulin et al., 2011). Dosages of 2 mg/kg every 12 hours may provide therapeutic concentrations in dogs. Therapeutic plasma concentrations of desmethyldiazepam are usually greater than 1 μg/ml.

As mentioned for clonazepam, clorazepate is also used in cats as an alternative to diazepam. There has not been much experience in cats, but doses in the range of 3.75 to 7.5 mg per cat once daily have been used.

Felbamate

Felbamate (Felbatol) has been used in dogs that are refractory to other anticonvulsant drugs. Since there is less experience with felbamate and other drugs are now available, it is usually considered as a last resort (Bhatti et al., 2015). The action is not completely understood, but it is an antagonist at the *N*-methyl-D-aspartate (NMDA) receptor–ionophore complex. Antagonism of NMDA may block effects of excitatory amino acids and suppress seizure activity (increase seizure threshold and decrease seizure spread). It addition there may be some neuroprotective effects from antagonizing excitatory amino acids. This unique mechanism of action has been used to argue that it may be considered in patients that are refractory to other anticonvulsant drugs.

Pharmacokinetics

In dogs the half-life has been reported to be approximately 5–6 hours (Adusumalli et al., 1992). The pharmacokinetics have not been examined in other animals.

Clinical Use

The initial dose in dogs is approximately 15–20 mg/kg q 8 h, orally. In practice, the starting dose is 200 mg/dog orally q 8 h (small dogs) and increases by 200 mg per week until seizures are controlled to a maximum of 600 mg/dog q 8 h. For large dogs, start with 400 mg/dog q 8 h and increase gradually to a maximum of 1,200 mg/dog q 8 h. (This dose range is approximately 15–65 mg/kg q 8 h.) Felbamate has induced its own metabolism in dogs; therefore, there may be a need to increase doses as therapy progresses. Felbamate human formulations (Felbatol®) are available in 120/ml oral liquid and 400 and 600 mg tablets.

Adverse Effects

Adverse reactions have not yet been documented with clinical use in dogs, but it has not been used frequently. It does not seem to produce the sedation and behavior changes that other drugs have been known to cause. Toxic signs have not been seen in dogs unless the dose exceeded 300 mg/kg/day. In people there are strong warnings on the label. Use in humans has caused aplastic anemia and severe hepatic failure resulting in death. In people it has been shown to increase phenobarbital concentrations by 20–30% so careful monitoring of phenobarbital concentrations is suggested.

Gabapentin

Gabapentin (Neurontin and generic brands) has been used in dogs and cats to control seizures when other anticonvulsant drugs have not been effective, or when others have been too toxic. It is ordinarily used as an add-on treatment; there are not studies reported in which it has been used as monotherapy. Despite this use, there is little evidence available in dogs or cats to show that it is effective. Subsequently, it was not included as a recommended drug by the ACVIM consensus group (Podell et al., 2016).

Gabapentin is a structural analog of GABA, but the mechanism of action as an anticonvulsant is not entirely known. It does not interact with GABA receptors and is not a GABA agonist, and does not affect GABA uptake or degradation. It also does not interfere with sodium-dependent channels or exhibit affinity for other neurotransmitter receptors such as those affected by benzodiazepines, glutamate, dopamine, or NMDA.

The same action that is responsible for its use for treating neuropathic pain may also explain its anticonvulsant activity. The mechanism of action for treating neuropathic pain appears to be via blocking calcium-dependent channels. Gabapentin inhibits the alpha-2-delta (α_2 Δ) subunit of the N-type voltage-dependent calcium channel on neurons. After binding to the α_2 Δ subunit it reduces calcium influx that is needed for release of neurotransmitters – specifically excitatory amino acids – from presynaptic neurons. This channel becomes up-regulated when nerves are stimulated, such as in epileptic conditions or associated with neuropathology. Blocking the channels has little effect on normal neurons, but appears to suppress stimulated neurons.

Pharmacokinetics

Gabapentin is absorbed in dogs with systemic oral availability that is practically complete (80% or greater) and is not affected by food. Compared to the elimination in people, gabapentin has a short half-life of 2–4 hours in dogs (Radulovic et al., 1995; KuKanich and Cohen, 2011). The systemic clearance resembles renal clearance values in dogs of 2–3 ml/kg/min (Radulovic et al., 1995), which has led to the conclusion that gabapentin is excreted by renal mechanisms and does not rely on hepatic biotransformation, except for small biotransformation in dogs to

N-methylgabapentin. Therefore, it has been used in animals when hepatic disease or impaired metabolism is a concern. Protein binding in dogs is negligible (Radulovic et al., 1995).

The pharmacokinetics in cats was studied at a dose of 4 mg/kg IV and 10 mg/kg oral (Siao et al., 2010). The oral absorption was 89%, but was variable among cats. The average oral half-life was approximately 3 hours (similar to dogs). This study predicted an effective oral dose in cats of 3 mg/kg every 6 hours.

Because of interest in using gabapentin in horses for chronic pain, pharmacokinetics were studied after an oral administration of 5 mg/kg (Dirikolu et al., 2008). Oral clearance was high and the half-life was 3.4 hours (similar to dogs and cats). In another study the oral absorption of 20 mg/kg was only 16%, but the half-life was longer (approximately 8 hours), and the horses tolerated it well (Terry et al., 2010).

Lipophilicity and penetration: The volume of distribution is small compared to other anticonvulsants (0.158 l/kg) (Radulovic et al., 1995), an octanol/water partition coefficient (Log P) of only −1.10 and a partition coefficient at pH 6–8.5 (Log D) of only −1.44. These values indicate that lipophilicity is lower than what is needed to penetrate the blood–brain barrier. Therefore, gabapentin must rely on a carrier for penetration to the CNS. Gabapentin mimics an α-amino acid and utilizes the large amino acid transporter to penetrate the brain (Jolliet-Riant and Tillement, 1999).

Clinical Use

Gabapentin is available in 100, 300, and 400-mg capsules; 100, 300, 400, 600, and 800-mg scored tablets; and 50 mg/ml oral solution. The oral solutions contains xylitol, which is known to be toxic to dogs. The dose of oral solution administered to dogs must consider the amount of xylitol delivered, and avoid the use of this product if the dog is already receiving xylitol-containing medications.

Anticonvulsant use: Gabapentin is used primarily for refractory seizures that have not responded to other drugs. It has not been used alone as an anticonvulsant in animals. In people the dose varies from 900 to 1,800 mg per person per day, and up to 3,600 mg per day. In dogs the most common dose (derived empirically) has been 10–20 mg/kg orally, every 6–8 hours. A study in greyhound dogs predicted that a dose of 10–20 mg/kg oral, every 8 hours would produce concentrations at an effective level of 2 μg/ml (KuKanich and Cohen, 1011). In cats, it has been administered at a dose of 5–10 mg/kg per day orally, increasing the frequency to twice daily.

Use for treatment of pain: Another use of gabapentin in animals is for treatment of pain syndromes – particularly those identified with neuropathic pain. The mechanism responsible for this effect is via blockade of the calcium channels that may be up-regulated in painful neuropathic conditions, as discussed previously. This use stems from the experience in people in which gabapentin is used to treat neuropathic pain caused by postherpetic neuralgia (shingles), diabetic neuropathy, and other types of pain associated with neuralgia. Neuropathic pain is difficult to diagnose in animals, but may result from nerve pathology linked to another underlying disease. There are no well-controlled studies that have demonstrated effective neuropathic pain relief from gabapentin in dogs. A clinical postoperative pain study failed to demonstrate effectiveness (Wagner et al., 2010), and it failed to demonstrate a significant benefit in dogs for treating pain associated with intervertebral disc surgery (Aghighi et al., 2012). The use of gabapentin has also become popular in cats for treating chronic pain, but antinociceptive studies failed to demonstrate an effect (Pypendop et al., 2010). For neuropathic pain the dose used is 10–15 mg/kg q 8 h PO, and increased as necessary to levels similar to the anticonvulsant dose.

Gabapentin also was used to treat neuropathic pain in horses associated with laminitis and other conditions. After a dose of 2.5 mg/kg orally every 12 hours, gabapentin subjectively appeared to relieve pain in a horse that was secondary to surgery (Davis et al., 2007). It has also been used in racing horses, even though it is a Class 3 substance for race horses. Despite this growing interest for its use in horses, and few adverse effects reported, it had no significant effect for reducing lameness level compared to the placebo at an oral dose of 5 and 10 mg/kg three times daily in horses with chronic pain (Caldwell et al., 2015).

Adverse Effects

There have been no reported serious safety problems with gabapentin in animals during routine use. Sedation and ataxia are reported as the only significant adverse effects. In people a withdrawal syndrome from abrupt discontinuation has been described, but it is not reported in animals.

Pregabalin

Another drug related to gabapentin is pregabalin (Lyrica), but pregabalin is a classified as a controlled substance in the USA and gabapentin is not. It is used in people for neuropathic pain similar to gabapentin use. There is some information on its use in small animals, but it is limited. One study (Dewey et al., 2009) in a small number of dogs showed potential benefit as an adjunct drug in addition to phenobarbital and bromide for refractory epilepsy. The dose used in that study was 3–4 mg/kg oral every 8 hours.

The pharmacokinetics have been studied in dogs (Salazar et al., 2009) and were similar to people with a half-life of approximately 7 hours. Their study suggested a dose of 4 mg/kg every 12 hours would maintain the drug concentrations in an effective range (2.8–8.2 μg/ml) for treatment of pain and epilepsy. Preliminary studies on the pharmacokinetics in cats suggest a dose of 1–2 mg/kg every 12 hours and increased to 4 mg/kg every 12 hours orally (Cautela et al., 2010). Because oral absorption of gabapentin is low in horses (16%), pregabalin was studied to determine if absorption would be better. In horses after a dose of 4 mg/kg the oral absorption was 98% and half-life approximately 8 hours (Mullen et al., 2013). They predicted a dose of 4 mg/kg oral to horses every 8 hours would produce plasma drug concentrations in a range considered effective for people.

Levetiracetam

Levetiracetam (Keppra and generic) is another anticonvulsant drug used in people that has been adapted for use in dogs and cats. Levetiracetam is structurally and mechanistically different from other anticonvulsant drug classes (Figure 17.1). The mechanism of action of levetiracetam is not completely understood, but it has significant anticonvulsant activity in people for several types of seizures. It does not appear to affect membrane channels, GABA, membrane receptor activity, or glutamate receptor neurotransmission. Levetiracetam is capable of suppressing seizure activity without affecting normal neuronal excitability. One proposed mechanism of action is through binding to a presynaptic protein (synaptic vesicle 2a) and modulating voltage-gated calcium-dependent neurotransmitter release from vesicles in neurons. The site of binding is exclusively in the CNS, without any known peripheral effects.

The pharmacokinetics have been studied sufficiently to recommend dosing protocols to maintain plasma concentrations at a level that is considered effective in people (Isoherranen et al., 2001; Dewey et al., 2008; Patterson et al., 2008; Moore et al., 2010, 2011). It has good oral absorption, but a short half-life necessitating dosing at least every 8 hours. It has not been considered as monotherapy treatment for dogs or cats. It is usually used as an add-on, for patients with refractory epilepsy who are already receiving phenobarbital or bromide.

According to Isoherranen et al. (2001) levetiracetam is the ethyl analogue of piracetam, which has been used, among other things, for cognition enhancement in elderly people. Levetiracetam is the *S*-isomer of a chiral drug that exists in two enantiomers. Only the *S*-form, levetiracetam, has anticonvulsant activity. It has high solubility (>1 grams/ml), and octanol/water partition coefficient (Log D at 7.4) of −0.64.

Pharmacokinetics

In pharmacokinetic studies performed in dogs with IV, IM, and oral doses (Isoherranen et al., 2001; Dewey et al., 2008; Patterson et al., 2008; Moore et al., 2010, 2011), levetiracetam had 100% absorption from all routes of administration. Protein binding of levetiracetam is small (<10%); therefore, drugs or conditions that affect plasma protein will not alter levetiracetam pharmacokinetics. The volume of distribution ranged from 0.45 to 0.89 l/kg, depending on the study. With a half-life that ranged from 3 to 4.5 hours, it can be administered three times daily and maintain plasma concentrations that are within the range cited for humans as effective (Moore et al., 2010). After multiple doses for 6 days, there was no change in pharmacokinetic parameters (Moore et al., 2010).

Levetiracetam does not undergo significant hepatic metabolism, and it is mostly excreted unchanged in the urine. Although drug interactions with phenobarbital have been documented (see Section Adverse Effects and Interactions), liver disease is not expected to affect its pharmacokinetics. This drug has been one of the preferred drugs when it is anticipated that liver function may be altered by other drugs or diseases.

Pharmacokinetics in cats have demonstrated 100% oral absorption and a short half-life of approximately 3 hours (Carnes et al., 2011; Dewey et al., 2005); however, the half-life was variable among cats in a clinical study (Bailey et al., 2008).

Clinical Use

Levetiracetam is used clinically in dogs for refractory epilepsy when other drugs have not been effective, often as an add-on to phenobarbital and/or bromide therapy (Podell et al., 2016; Bhatti et al., 2015). Clinical studies have revealed some initial success, but long-term benefit is uncertain. In a small study (Volk et al., 2008), most dogs responded initially with a decrease in seizure frequency, but most responders had an increase in seizure frequency after 4–8 months of continued treatment. In a retrospective study (Packer et al., 2015), it was effective in most dogs administered either as maintenance treatment or as a pulse treatment, but in another clinical study, it was not effective in a small number of dogs compared to placebo when added to other anticonvulsant treatments in dogs with refractory epilepsy (Muñana et al., 2012). The ACVIM consensus panel gave it a low rating for monotherapy treatment but a better grade for add-on therapy.

Levetiracetam (Keppra and generic) is available in 250, 500, and 750-mg tablets. The usual human dose is 500 mg q 12 h. In dogs, the typical dose is 20 mg/kg orally, every 8 hours, which will maintain plasma concentrations within a range that is reported to produce anticonvulsant activity in people (Moore et al., 2010). In dogs receiving pretreatment with levetiracetam to prevent postoperative seizures from portosystemic shunt surgery, a dose of 20 mg/kg every 8 hours significantly reduced the risk of postoperative seizures and death (Fryer et al., 2011).

The effective plasma concentrations in dogs and cats are not known, but doses have been aimed at reaching the effective plasma concentrations in people of 12–46 μg/ml. There are also extended-release generic formulations for people that have been used in dogs. Although the prolongation of effective plasma concentrations was minor from the extended-release formulation, in some dogs it can be administered once every 12 hours and maintain plasma drug concentrations above the suggested therapeutic level. The extended-release tablets (500 and 750 mg) contains levetiracetam in a drug release controlling polymer. The tablets should not be crushed or broken so that extended-release properties are maintained. There is also an injectable formulation (100 mg/ml) that can be administered IV, and shown to be effective for emergency treatment of seizures (Hardy et al., 2012). The initial IV dose in the study was 30 mg/kg, and could be safely increased to 60 mg/kg. Rectal administration of the IV solution also has been explored for dogs. Although the rectal dose must be higher than oral administration (40 mg/kg for dogs), absorption from the rectal route can attain effective concentrations (Peters et al., 2014). In large dogs, this may be impractical because of the large volume required to administer an effective dose.

There has been limited evaluation of levetiracetam in a small number of cats (Bailey et al., 2008; Dewey et al., 2005). At 20 mg/kg q 8 h, orally, it was well tolerated and effective in some cats as an adjunct to phenobarbital treatment. To maintain effective concentrations, higher doses may be needed in some cats (Carnes et al., 2011). A syndrome known as audiogenic reflex seizures in cats has been described in which seizures may be triggered by high-pitch sounds (Lowrie et al., 2016). Apparently the cats with this form of seizures respond much better to administration of levetiracetam than phenobarbital. The efficacy for this syndrome may be related to levetiracetam's affinity for the synaptic vesicle that mediates the anticonvulsant effect.

Adverse Effects and Interactions

Few adverse effects have been reported in dogs and cats at the currently recommended dosages. Some dogs may show sedation, ataxia, restlessness, and gastrointestinal disturbances, but in these instances it was always administered with at least one other anticonvulsant. Intravenous levetiracetam has been administered to dogs at doses of 60 mg/kg without reported adverse effects (Dewey et al., 2008; Patterson et al., 2008). At high doses in excess of 600 mg/kg/day, nausea and vomiting in dogs has been observed, but no deaths. The most common adverse effect in cats was lethargy. In people, adverse effects are uncommon and may be idiosyncratic because there has been no relationship between plasma drug concentrations and adverse events (Contin et al., 2004).

Because it does not rely on extensive hepatic metabolism by cytochrome P450 enzymes, most drug interactions are uncommon. However, studies in dogs (Moore et al., 2011) showed a significant decrease in plasma concentration, shorter half-life and more rapid clearance of levetiracetam when it was administered with phenobarbital (enzyme induction by phenobarbital is discussed in Section Phenobarbital, Pharmacokinetics). Studies in people have shown that elderly people may have lower clearance, and some anticonvulsant drugs have induced a more rapid clearance (Hirsch et al., 2007; Contin et al., 2004; May et al., 2003). Lower clearance in the elderly was associated with decreased creatinine clearance.

Zonisamide

Zonisamide (Zonebran) is a human anticonvulsant that has been used in some canine epileptics and some cats that are refractory to other drugs. Zonisamide is chemically classified as a sulfonamide (Figure 17.1), but unrelated to other anticonvulsants. It has a high pKa of 10.2, a low molecular weight of 212.23, and solubility in water that is close to 1 mg/ml. It can suppress seizures induced by a variety of stimuli. Mechanism of action is unclear. It does not affect GABA-mediated mechanisms, but may block voltage-gated sodium and calcium channels (T-type calcium channels). The result of these actions is to stabilize neuronal membranes and suppress neuronal hyperactivity.

Pharmacokinetics

Because of growing interest for using zonisamide as an anticonvulsant in animals, more data have become available. In people, it has low (40%) protein binding, a high volume of distribution, low clearance (0.3 ml/kg/min), and half-life of 63 hours in plasma and 105 hours in red blood cells (RBCs). Levels are much higher in RBCs (eightfold higher), which are sometimes used for drug assays. It is excreted primarily in urine as the parent drug or as a glucuronide metabolite. It also undergoes *N*-acetylation. Because these two mechanisms – *N*-acetylation and glucuronidation – are deficient in dogs and cats, respectively, this may contribute to important pharmacokinetic differences in dogs and cats compared to people. Dogs are known to have adverse reactions to sulfonamide antimicrobial drugs, which may be related to their deficiency in *N*-acetylation metabolism (discussed in more detail in Chapter 32).

The disposition of zonisamide has been studied in dogs (Matsumoto et al., 1983; Boothe and Perkins, 2008). Oral absorption in dogs was 68%, with a half-life of 15–17 hours in plasma, depending on the study and route, but longer in red blood cells (44–46 hours in whole blood, and 91 hours in RBCs). Protein binding averaged 39.5% across a range of concentrations (Boothe and Perkins, 2008). In cats the mean half-life was longer than in dogs (31.5 hours) after a dose of 10 mg/kg (Hasegawa et al., 2008).

Clinical Use

In dogs, initial recommended doses of zonisamide in the range of 6–10 mg/kg twice daily orally have been recommended. But based on a pharmacokinetic study (Boothe and Perkins, 2008), these doses may be too high and they recommended a dose of 3 mg/kg oral, twice daily to reach concentrations in the desired range of 15 μg/ml. Phenobarbital may increase clearance (by approximately 50%). Therefore, if administered in combination with phenobarbital a higher dose of 7–10 mg/kg twice daily may be considered (Orito et al., 2008). It is available in 100-mg capsules.

It rarely used alone and is reserved for treating epilepsy in animals as an add-on to other drugs. In clinical studies with small numbers of dogs treated for refractory epilepsy along with other drugs, it has been effective in most dogs. The ACVIM consensus group rated it low for monotherapy treatment and moderate for add-on therapy. There have been three studies of efficacy reported in animals. In the study by Dewey et al. (2004) 12 dogs with refractory epilepsy were treated with an average dose of 8.9 mg/kg every 12 hours orally; 58% of dogs responded favorably, but 5 of 12 dogs actually had an increase in seizure frequency. In the study by von Klopmann et al. (2007) data from 11 dogs were evaluated. The dogs were administered 10 mg/kg twice daily for treatment of refractory epilepsy. Of 11 dogs, 9 were responders. In three of the dogs there was a decrease in response over time, which may reflect tolerance that develops with long-term treatment.

Zonisamide is typically not monitored clinically, but effective concentrations in dogs were reported to be above 12.6 μg/ml (Masuda et al., 1979). Neurotoxic effects in dogs were seen at concentrations above 96 μg/ml. In the study by Dewey et al. (2004) cited above, the effective concentrations were 10–40 μg/ml and similarly in the report by von Klopmann et al. (2007) were 15–38 μg/ml. Most veterinary neurologists now recommend a desired plasma concentration of 10–40 μg/ml based on extrapolation from people (Muñana, 2013; Bhatti et al., 2015; Podell et al., 2016). When measuring plasma drug concentrations, one should be sure to avoid hemolysis of red blood cells in the sample.

In cats there has been more limited use of zonisamide compared to dogs. A dose of 5 mg/kg oral, every 12 to 24 hours has been used.

Adverse Effects

The administration of zonisamide to animals has been infrequent; therefore, there is not a full appreciation for the incidence of adverse effects. In clinical studies, the adverse effects reported were sedation (transient), ataxia, and vomiting (Dewey et al., 2004). Rare idiosyncratic hepatic injury and renal tubular acidosis have been observed in some dogs. There were also some adverse effects that occurred that are similar to those caused by sulfonamides. Because of structural similarity between zonisamide and sulfonamides, this may be of concern.

In safety studies, dogs tolerated doses of 10–175 mg/kg for 52 weeks (pharmaceutical company data). At doses of 1,000 mg/kg to dogs, there was a decrease of locomotor movement, ataxia, and vomiting (pharmaceutical company data). In a pharmacokinetic and safety study (Boothe and Perkins, 2008), clinical laboratory tests remained normal after 8 weeks, but thyroxine concentrations (T_4) may be lower in some dogs. (Sulfonamide-like drugs are known to affect thyroxine synthesis in dogs.)

In one study in cats, safety was evaluated after 9 weeks of daily administration of 20 mg/kg (Hasegawa et al., 2008). Lethargy, anorexia and gastrointestinal problems were observed. Mild gastrointestinal problems observed in half of the cats. Some cats had neurological reactions at high doses.

Bromide (Potassium and Sodium Bromide)

Bromide is the oldest, yet most chemically simple, of the anticonvulsants. It was used in people as early as the mid-1800s and its use was first described in dogs as early as 1907. Because it is toxic in people, it was replaced by other anticonvulsants after the introduction of phenobarbital in 1918. There are no commercial formulations available in the USA, but some are approved in other countries. In the USA, the dose formulations used in animals are prepared by compounding from the active chemical substance. It is now used commonly in dogs, but less common in cats (Podell and Fenner, 1994; Trepanier, 1995). The exact mechanism of action is uncertain, but it appears to stabilize neuronal cell membranes. It may enter the chloride channel and reach intracellular levels in the postsynaptic membrane to hyperpolarizes the neuronal cell membrane.

Pharmacokinetics

Oral absorption of the compounded products is approximately 46%. The volume of distribution (0.45 l/kg) suggests equal distribution in body water. The half-life in dogs is approximately 25 days, but can be variable. Elimination rate can vary depending on the patient's diet (see Section Effect of Diet). Because the half-life is long, chronic daily administration will be necessary for this drug to accumulate to steady-state plasma concentrations. However, during the accumulation phase (loading dose period) the half-life is shorter (15 days; March et al., 2002) which results in faster accumulation. The half-life in cats appears to be a bit less than dogs – about 14 days, and perhaps as short as 10 days (Boothe et al., 2002). Bromide is entirely excreted by the kidneys; therefore, liver impairment or drugs that affect cytochrome P450 enzymes will not affect clearance.

Clinical Use in Dogs

Bromide has been used in combination with phenobarbital to treat refractory seizures, and also has been used as monotherapy (single drug). It is not as effective as monotherapy for treating epilepsy in dogs as phenobarbital (Boothe et al., 2012), but can be acceptable in some dogs. When bromide is administered as a single drug, bromide doses may need to be higher compared to administering bromide with phenobarbital. When used with phenobarbital, phenobarbital doses can be decreased by as much as one-half. One study reported that, in 19% of dogs receiving phenobarbital and bromide, eventually the phenobarbital was discontinued while still maintaining seizure control (Trepanier et al., 1998).

The ACVIM consensus panel (Podell et al., 2016) gave bromide a moderate rating for both monotherapy and add-on treatment. Most often, bromide is used as add-on therapy in refractory epileptics who are receiving other anticonvulsant medications. When potassium bromide (KBr) has been used to treat canine epileptics that have not responded to phenobarbital alone, success rates have been 60% and one author reported as high as 72% improvement in seizure control (Trepanier et al., 1998). After several years of using bromide for treating epilepsy in dogs, a comprehensive review (Baird-Heinz et al., 2012) concluded that "Potassium bromide is not an appropriate therapeutic choice for every dog…" The authors recognized that it can be helpful for some dogs, but also emphasized the importance of careful dosing, monitoring of serum concentrations, and observation for adverse effects to ensure safe and effective therapy.

Maintenance doses: Usually the potassium salt of bromide is used, but sodium bromide also can be substituted. Most veterinary compounding pharmacies have recipes for preparing an oral solution and it is relatively inexpensive. Compounded forms have been tested and shown to be stable for several months. However, adherence to good compounding practices is important to ensure safe and effective dosing. The typical dosage of potassium bromide for dogs is 30–40 mg/kg, orally, once per day. (This translates to 20–27 mg/kg of bromide once per day.) The lower doses are more common when used with phenobarbital, while the higher doses are given when monotherapy is used.

There is high variability among animals with respect to absorption and excretion. Therefore, it is suggested that each patient be monitored for signs of toxicity (ataxia, CNS depression), as well as plasma concentration monitoring, and the dose adjusted if necessary.

Loading doses: Loading doses of 600 mg/kg orally over 3–4 days have been administered in patients that need therapeutic concentrations quickly in the range of 1.0–1.5 mg/ml. If dogs are receiving bromide alone (without phenobarbital), use a starting dose of 40–50 mg/kg/day. In one study, March and colleagues (2002) administered loading doses of 30 mg/kg twice daily for 115 days to achieve steady-state concentrations in the range of 200–300 mg/dl.

In some cases it has been necessary to administer sodium bromide IV as a loading dose. This has been accomplished by mixing sodium bromide (potassium bromide may be responsible for unsafe potassium concentrations in some patients if administered IV), in a solution to deliver an initial dose of 600–1,200 mg/kg over approximately 8 hours. If the plasma concentration is still in the low range, an additional IV loading dose can be administered.

Effect of Diet

Diets high in chloride will cause bromide to be excreted more rapidly (as much as 50% decrease in half-life with high chloride diets); therefore, the diet should be kept constant throughout therapy, or monitor serum bromide concentrations each time the diet is changed. Some prescription diets have either high or restricted chloride content and patients receiving these diets may need dose adjustments.

Clinical Use in Cats

A report and accompanying review evaluated use of bromide in cats (Boothe et al., 2002). In that report, the authors identified a half-life in cats of only 11.2 days. An evaluation of the clinical use showed that there was inadequate seizure control in approximately half of the cats, despite serum concentrations that are reported to be effective in dogs. The most common dose was 30 mg/kg per day. More importantly, approximately half of the cats developed adverse reactions. The most common adverse effect was coughing (see Section Side Effects and Adverse Effects), and follow-up case reports showing bromide-associated lower airway disease in cats concluded that "using bromide for seizure control in cats cannot be recommended" (Bertolani et al., 2012).

Therapeutic Monitoring

Plasma concentrations can be measured at most veterinary diagnostic laboratories. It is a relatively easy measurement in plasma, usually based on the gold chloride reaction and observed color reaction. Ordinarily, effective concentrations are reported as between 1 and 2 mg/ml (100–200 mg/dl). If concentrations are less than 1.0 mg/ml, one should increase the dose. If bromide is used as the sole anticonvulsant (without phenobarbital) concentrations as high as 2–3 mg/ml (200–300 mg/dl) may be necessary.

Side Effects and Adverse Effects

Side effects of polyphagia, polyuria/polydipsia, and behavior changes have been reported in some dogs. Bromide toxicosis (bromism) has been reported with high serum concentrations and/or high doses (Rossmeisl and Inzana, 2009). The signs of toxicosis are largely related to CNS depression and include depression, weakness, ataxia, and decreased proprioception. These signs can be alleviated with a decrease in dose, or diuresis to increase renal elimination. The authors of this study (Rossmeisl and Inzana, 2009) indicated that the most common reason for development of bromism was suboptimal monitoring of serum concentrations that resulted in concentrations that were too high. They also indicated that mistakes during compounding could result in dosing errors. Bromide can cause some stomach upset in some dogs, and administration with food may alleviate this problem. There is some evidence that bromide treatment, or the combination of phenobarbital and bromide can increase the risk of pancreatitis in dogs, but clinical confirmation of this risk has not been shown (Steiner et al., 2008). A unique sign of high bromide concentrations is joint stiffness in the rear limbs. Some animals may show signs of sedation for the first 3 weeks of therapy, but develop tolerance with chronic treatment.

In cats, respiratory signs resembling feline asthma (coughing) were identified (Boothe et al., 2002). The mechanism is not known, but it is not believed to be an allergic reaction, but rather a result of airway inflammation. A follow-up case series reported bromide-associated lower airway disease in cats treated with bromide (Bertolani et al., 2012). In some cats there was neutrophilic and eosinophilic inflammation of the airways. The authors concluded that bromide may induce severe and irreversible lower airway disease in some cases, and complete resolution of clinical signs did not occur until bromide therapy was discontinued.

Drug Interactions

When an animal is receiving potassium bromide therapy, it may cause a falsely elevated chloride serum measurement with some assays.

Drugs Affecting Animal Behavior

Margaret E. Gruen, Barbara L. Sherman, and Mark G. Papich

Introduction

Over the past decade, the use of drugs to influence animal behavior has expanded commensurate with that of human behavioral medicine (Crowell-Davis and Murray, 2006; Simpson and Papich, 2003). Drugs, in combination with behavior modification, have been used to manage difficult animal behavior problems. Often these problems are those insufficiently responsive to nonpharmacological approaches alone and may impact the animal's health and welfare. In a general way, drugs may decrease arousal, excitability, and impulsivity and promote behavioral calming. More specifically, behavioral drugs may be used to attenuate repetitive compulsive behaviors, modulate aggression, and help manage organic states (Stein et al., 1994). Psychotropic drugs may be used to decrease the latency to response to behavioral treatment (King et al., 2000b).

The use of behavioral drugs to reduce fears and anxieties may enhance animal welfare and promote safe and humane handling. Extrapolating from the reports of humans who suffer from anxiety disorders and from our direct observations, highly anxious or fearful animals suffer as well and should be treated, behaviorally and pharmacologically, consistent with our mission as veterinarians to reduce animal suffering. We suggest that, particularly for anxiety-related disorders, pharmacological treatment should be considered as a first, rather than last, resort.

This chapter focuses on commonly used behavioral drugs, their presumed mechanism of action, their side effects and their application to clinical veterinary practice. In addition, some new agents, with potential for use in veterinary behavior, are introduced. Although the activities of behavioral drugs have been elucidated in vitro, our knowledge of their activity in the brain of humans or nonhuman animals remains imperfect. Radioactive labeling, advanced imaging, and other techniques have revealed the remarkable complexity of the brain and the interrelationships of systems previously considered distinct. For example, there is increasing evidence that affective disorders are modulated by neuroactive steroids that, in turn, modulate specific neurotransmitters, including those described in this chapter (Eser et al., 2006). In spite of recent expansion in our understanding and application of behavioral drugs, behavioral pharmacology remains in its infancy due to the complexity and multidimensional aspects of behavior.

With few exceptions, the drugs discussed herein are approved for use in humans for the treatment of behavioral disorders; their use in animals is extralabel (Simpson and Voith, 1997). Without an approved claim, it has fallen upon veterinary behaviorists, pharmacologists, and other specialists to examine the relevant data and conduct studies to examine the published record on these medications to predict clinical use and response. One of the greatest challenges in evaluating the studies published in human medicine or from laboratory animal studies is to interpret the data in light of the various species differences that exist in pharmacokinetics, drug metabolism, receptor sensitivity, and susceptibility to toxicosis.

Pharmacokinetic Issues for Behavior Drugs

Pharmacokinetics is covered in more detail in this book in earlier chapters (Chapters 2 and 3). Pharmacokinetics is the science that describes the effect of the body on a drug and a description of the absorption, distribution, metabolism, and elimination (Janicak et al., 2011). In this section are some comments regarding the importance of pharmacokinetic issues to behavior drug therapy. When there is a relationship of the plasma or serum drug concentrations to clinical effect, pharmacokinetics can be helpful to predict pharmacological response. This becomes particularly important when we have few controlled clinical trials of drugs in animals, but comparative pharmacokinetic data.

Absorption, Metabolism, Clearance, and Distribution

Bioavailability of a drug depends on both the extent and rate of drug absorption. Since most behavior drugs discussed in this chapter are administered orally, absorption becomes a critical pharmacokinetic parameter. Drug absorption is determined by examining the relative concentrations in plasma or serum. These concentrations serve as a surrogate to predict clinical response because the availability of a drug to the central nervous system cannot be easily measured.

Drugs administered orally can be absorbed quickly and avoid significant metabolism, be poorly absorbed because of unfavorable dissolution or solubility, or be absorbed from the gastrointestinal tract (GIT) and then undergo first-pass metabolism, which is the process of intestinal or hepatic metabolism prior to reaching systemic circulation.

Many of the behavior drugs to be discussed in this article are weak bases, for example, the substituted amines that are the tricyclic antidepressants and other centrally acting drugs. These weak bases generally have good lipophilicity, but poor water solubility. However, most are formulated as water-soluble salts (hydrochloride salts of clomipramine, fluoxetine, buspirone). This allows for more rapid dissolution in the GIT, followed by good permeability in the intestine. Subsequently, the oral absorption of most of these drugs is good. However, these drugs – being lipophilic – are also subject to enzyme metabolism in the intestine and liver. For some drugs, extensive intestinal and hepatic metabolism may render these drugs susceptible to the first-pass metabolic effects, which reduces the overall systemic availability.

Drug metabolism is the process whereby drugs are metabolized to active and inactive metabolites or an inactive drug can be metabolized to an active drug (if administered as a prodrug). For the drugs discussed in this chapter, the metabolic fate is determined primarily by hepatic and intestinal metabolism. To our knowledge, there are few drugs used in behavior therapy that are affected much by renal clearance, although the kidneys may be the ultimate route of elimination for conjugated water-soluble metabolites.

Many behavioral drugs are substrates for, or affect, cytochrome P450 (CYP) enzymes, which are microsomal drug-metabolizing enzymes (DeVane, 1999; Janicak et al., 2011) located primarily in the liver and GIT. These enzymes have potential for important pharmacokinetic drug–drug interactions. They are designated by family, subfamily, and isoforms by a number and letter sequence (Tables 18.1 and 18.2). In humans the important CYP enzymes include CYP1A2, CYP2C9-10, CYP2C19, CYP2D6, and CYP3A3/4. The enzymes CYP3A3/4 and CYP2D6 are responsible in humans for 50% and 30%, respectively, of known oxidative drug metabolism. Because these enzymes can be both induced and inhibited by certain drugs, such as those classified as antidepressants, concentrations of other drugs, metabolized by the same CYP 450 enzymes, will increase. For example, in humans fluoxetine and paroxetine inhibit CYP2D6, important in the oxidative metabolism of the tricyclic antidepressants (TCAs). When fluoxetine or paroxetine is used in combination with a TCA, a significant increase of the TCA plasma concentration occurs, potentially causing toxicity unless the TCA dose is reduced (Janicak et al., 1997).

One of the problems in veterinary medicine is that the enzymes, and subsequently their substrates and inhibitors, are not as well characterized as in human medicine (Chauret et al., 1997). The enzyme responsible for the greatest proportion of metabolism in humans is CYP3A4 oxidase. There are only low levels of CYP3A4 in dogs and cats, but other enzymes play a larger role (for example, CYP3A12) (Kuroha et al., 2002). Other enzymes present in dogs are the 1A, 2B, 2C, 3A, and 2D families and subfamilies (Chauret et al., 1997; Kuroha et al., 2002; Court, 2013). There are large interspecies differences in the P450-mediated metabolism in dog and cat microsomes compared to human. The variation is in the metabolic activity, as well as the effect of specific inhibitors on P450 enzyme activity (Chauret et al., 1997). Information on the inhibitory activity of drugs on various enzyme systems in humans should not be broadly extrapolated to dogs and cats (Kuroha et al., 2002).

The other step in drug metabolism is a biosynthetic reaction called conjugation. Drug metabolic conjugation is the process whereby the drug or metabolite is linked with endogenous compounds such as amino acids, glucuronic acid, sulfate, glutathione, or acetyl (acetate). These polar conjugates are more water soluble and more easily excreted than the parent compound. The conjugated products are usually inactive, but there are exceptions.

Just as with the other metabolic reactions, there are tremendous species differences in the conjugation reactions. Dogs lack the ability to acetylate drugs such as sulfonamides; cats have a deficient ability to form glucuronide metabolites with drugs such as salicylate and phenols (such as with acetaminophen metabolites).

The rate of hepatic metabolism is measured by hepatic clearance. Clearance is one of the determinants of elimination half-life (T1/2), the time needed for plasma drug concentrations to decrease by 50% (Janicak et al., 2011). Drugs with short elimination half-lives must be given more frequently to maintain a consistent plasma concentration. With repeated dosing, these drugs also achieve steady-state more quickly. Usually after five half-lives, a drug reaches steady-state, the plasma concentration achieved as long as the dosing schedule or other metabolic processes remain constant. Once plasma

All doses are per os unless otherwise noted

steady-state is achieved, drug concentration in other tissues, such as the brain, is at equilibrium. The time to reach steady-state is relevant to the use of behavior drugs. Some drugs, such as diazepam in the dog, have short half-lives (T1/2 less than 1 hour) (Papich and Alcorn, 1995). Unless administered more frequently than once every five half-lives, these drugs will never reach a steady-state. On the other hand, drugs with long half-lives will accumulate with chronic dosing and attain steady-state in approximately five half-lives. But, if the half-life is 24 hours or longer, several days may be necessary before the drug accumulates to a level high enough to produce a consistent clinical response. This may be one reason that some antidepressant drugs do not have immediate effects when administered chronically in animals.

The physiological distribution of drugs is determined by their lipid solubility and protein binding. The higher the lipophilicity, the greater is the ability to distribute across biological lipid membranes, as long as plasma protein binding is not so high as to limit the diffusion. Because most behavior drugs are weak bases, protein binding is expected to be low for these drugs. However, this is only assumed, because there is little or no published data documenting the true plasma protein binding for these drugs in dogs and cats. Tissue protein binding, or intracellular trapping of drugs, can increase the distribution of drugs from the plasma to tissue compartment. Most of the behavior drugs are unionized and lipophilic at physiological pH. Some may be trapped in the brain or CSF owing to pH partitioning because these spaces are relatively more acidic than the plasma. Because the tissue concentrations may be high relative to plasma concentrations of these drugs, the apparent volume of distribution for this group of drugs is usually greater than 1.0 l/kg.

Relevant to the behavior drugs is the distribution across the blood–brain barrier (BBB). The BBB consists of unfenestrated capillaries, with tight junctions that prevent large or poorly lipophilic molecules from passing from the blood to the brain (Pardridge, 1999; Jolliet-Riant and Tillement, 1999). There is also a blood–CSF barrier, but it makes up a relatively smaller component to the distribution of drugs to the central nervous system. The BBB also is comprised of transmembrane pumps that effectively transport drugs (and probably other compounds) from the brain back to the blood stream. One of the best known of these transporters is p-glycoprotein. Some drugs are good substrates for p-glycoprotein and other drugs serve as inhibitors of these pumps (Jolliet-Riant and Tillement, 1999).

Neurotransmitters

Details of the autonomic nervous system function and transmission are covered in more detail in Chapters 6, 7, and 8. Presented here are some of the neurotransmitters that are most affected by behavior-modifying drugs. Behavioral drugs act either as stimulators (agonists) or blockers (antagonists) of neurotransmitter receptors, or as inhibitors of associated regulatory enzymes (Baldessarini, 1995; Stahl, 2013). Drugs that modulate naturally occurring neurosignals affect the monoamine neurotransmitters serotonin (5-hydroxytryptamine or 5HT), norepinephrine (NE), and dopamine (DA), as well as acetylcholine (ACh), glutamate, and γ-aminobutyric acid (GABA) receptors, among others. Neurotransmitters have multiple receptor subtypes distributed in specific areas of the body with which they interact. The

q HS, at bedtime.

most selective drugs mimic the natural neurotransmitter's action at only one receptor subtype. Other substances, such as circulating hormones, pituitary peptides, opioid peptides, and neurokinins can also affect behavior (Stahl, 2013).

At the cellular level, neurotransmission alters the function of postsynaptic target neurons. This process, in turn, affects gene expression (Stahl, 2013). The neurotransmitter released from the presynaptic neuron is considered the first messenger. It binds to its postsynaptic receptor and the bound neurotransmitter regulates a second messenger inside the cell of the postsynaptic neuron. This second messenger, in turn, forms transcription factors that, when activated, bind to regulatory regions of genes. This process activates RNA polymerase and the gene is transcribed into its mRNA, leading to translation of the corresponding protein. The protein can influence cellular processes that modulate behavior. Because multiple neurotransmitters are involved in CNS function, each working through multiple receptors, chemical signaling provides the features of both selectivity and amplification.

Discussed below are neurotransmitters or regulatory enzymes known to influence behavior and be affected by commonly used behavioral drugs. The monoamine neurotransmitters include norepinephrine, dopamine, and serotonin. It is now known that many neurons respond to more than one neurotransmitter, a process called *cotransmission* (Stahl, 2013). This may explain why multiple drugs in combination may be particularly effective and why some beneficial drugs act on more than one neurotransmitter. At this time, there is no rational treatment approach based on cotransmission. However, a strategic multiple drug program may enhance treatment success in the future.

Norepinephrine

Norepinephrine (NE) is derived from the amino acid tyrosine, which is transported from the blood and into each noradrenergic neuron by means of an active transport pump (Stahl, 2013). There, tyrosine is acted upon by three enzymes, eventually converting it to dopamine, and then to NE, which is stored in vesicles. NE can be broken down by monoamine oxidase (MAO), located in mitochondria, and catechol-*O*-methyl transferase (COMT), located outside the presynaptic nerve terminal. There are three postsynaptic receptors for NE that are important for the action of behavior-modifying drugs: β_1, α_1, and α_2. Norepinephrine has little activity on β_2 receptors. α_2 receptors are also found presynaptically. Called autoreceptors, they regulate NE release via a negative feedback system.

Most cell bodies for noradrenergic neurons are located in the locus coeruleus area of the brainstem. This region determines whether attention is focused on the external environment (as in response to a threat) or to internal signals (such as pain). There are many specific noradrenergic pathways in the brain, controlling both psychological and physiological activities. For example, projections from the locus coeruleus to the limbic cortex regulate emotions; projections in cardiovascular centers may control blood pressure.

Dopamine

Like norepinephrine, dopamine is synthesized intraneuronally from the amino acid tyrosine. Dopamine (DA) neurons lack the third enzyme that leads to conversion to norepinephrine. The same enzymes that break down norepinephrine (MAO and COMT) break down DA. There are at least five DA receptor subtypes. Best known is the DA_2 receptor, which is stimulated by dopaminergic agonists for the treatment of Parkinson's disease in humans and blocked by DA antagonist antipsychotics. Acepromazine, which is known to most veterinarians, is a well-known dopamine antagonist. Although DA_1, DA_3, and DA_4 receptors respond to antipsychotics, it is not clear to what extent they contribute to the behavioral effects of these drugs. When dopamine receptors are blocked, as with an antipsychotic drug, acetylcholine activity increases. This is because dopamine normally suppresses acetylcholine activity. An increase in acetylcholine activity can lead to extrapyramidal signs, discussed in Section Acetylcholine.

Serotonin

Serotonin, is also called 5-hydroxytryptomine or 5HT. The chemistry and pharmacology of serotonin and other transmitters are covered in more detail in Chapter 19. Abnormalities in central serotonin function have been hypothesized to underlie disturbances in mood, anxiety, satiety, cognition, aggression, and sexual drives (Tollefson and Rosenbaum, 1998). Drugs that enhance serotonin are among the most effective modulators of behavior (Simpson and Simpson, 1996a). Abnormalities in serotonin production or metabolism may underlie some behavior problems in companion animals. For example, dogs that exhibit affective (dominance type) aggression have significantly lower levels of serotonin metabolites in their cerebrospinal fluid than nonaggressive control dogs (Reisner et al., 1996). Canine compulsive disorder may be linked to 5HT dysfunction, based on the responsiveness of dogs that exhibit repetitive spinning, object licking, or light chasing to treatment with drugs that inhibit serotonin reuptake (Hewson et al., 1998a; Luescher, 2003).

For synthesis of serotonin, the amino acid tryptophan is transported into the brain from plasma. Two enzymes are involved in the conversion of tryptophan to 5HT. Analogous enzymes, transport pumps, and receptors exist in the 5HT neuron. Classification of 5HT receptors was reviewed thoroughly by Hoyer and colleagues (1994). There are two key presynaptic receptors, $5HT_{1A}$ and $5HT_{1D}$, and at least six postsynaptic receptors, $5HT_{1A}$, $5HT_{1D}$, $5HT_{2A}$, $5HT_{2C}$, $5HT_3$, and $5HT_4$ (Hoyer et al., 1994). As with NE and DA, presynaptic receptors act as autoreceptors that detect high concentrations of 5HT, inhibit further 5HT release, and slow 5HT neuronal impulse flow. Postsynaptic 5HT receptors regulate 5HT release from the presynaptic nerve ending. The $5HT_{2A}$, $5HT_{2C}$, and $5HT_3$ receptors are implicated in several serotonin pathways in the CNS (Hoyer et al., 1994). Although some $5HT_4$ receptors are in the CNS, their action is primarily localized to the gastrointestinal tract. Additional roles of this receptor on gastrointestinal function is discussed with specific drugs in Chapter 46. Serotonergic nuclei are localized to the raphe nucleus of the brainstem (Stahl, 2013). This area has projections to the frontal cortex, which may regulate mood; the basal ganglia, which may control movement and compulsive behaviors; and the limbic area, which may be involved in anxiety and panic.

There is evidence that the serotonin system may exert "tonic inhibition" on the central dopaminergic system (Tollefson and Rosenbaum, 1998). This may explain the occasional unexpected occurrence of extrapyramidal side effects during therapy with a selective serotonin reuptake inhibitor (Tollefson and Rosenbaum, 1998).

Acetylcholine

Acetylcholine (ACh) is formed in cholinergic neurons from two precursors: choline, derived from dietary sources, and acetyl coenzyme A, which is synthesized in the neuron. There are two major types of cholinergic receptors: nicotinic and muscarinic. Each of these is further divided into numerous receptor subtypes. There are five muscarinic receptor subtypes, M_1 through M_5. M_1 receptors are found at ganglia. M_3 and M_4 are found on smooth muscle and secretory organs, such as those of the GIT, and all five subtypes are found in the central nervous system. A nonspecific blocker of muscarinic receptors is atropine. One of the side effects of some behavior-modifying drugs (e.g. tricyclic antidepressants) is to block muscarinic receptors, thus producing cardiovascular, gastrointestinal, and other side effects. Additional discussion of the cholinergic nervous system is provided in Chapter 8.

Gamma-Aminobutyric Acid

Gamma amino butyric acid (GABA) is the major inhibitory neurotransmitter in the CNS, localized particularly in the cortex and thalamus (Sheehan and Raj, 2009). GABA is synthesized from the amino acid precursor glutamate. Glutamate participates in multiple metabolic functions. The GABA neuron has a presynaptic transporter similar to those of NE, DA, and 5HT. There are two subtypes of GABA: $GABA_A$ and $GABA_B$. $GABA_A$ subtype receptors are allosterically modulated by benzodiazepine receptors and others. Some of the anticonvulsant drugs that affect the GABA receptor are discussed in Chapter 17.

Major Drug Classes

Historically, behavioral drugs were classified according to their first human clinical application (for example, the antidepressant category), although such categorical descriptions have become functionally obsolete. Most behavioral drugs used in human and veterinary medicine have expanded their use well beyond their original clinical application. Traditionally, drugs are further classified according to their chemical structure and neurochemical activity. Tricyclic antidepressants (referring to a common chemical structure) and selective serotonin reuptake inhibitors (referring to neurochemical activity) are examples of drugs classified by their chemical structure and mechanism of action, respectively. The historic and functional drug classifications are retained here, since they provide a useful framework for our understanding of action and side effects of behavioral drugs. Drugs in the same category share many characteristics, including mechanism of action and common side effects. In addition, many reference sources utilize this traditional and logical categorization.

Antipsychotics

The antipsychotics include a number of structurally dissimilar drugs used in humans to treat psychosis, typified by conditions such as schizophrenia, affective disorder, and psychoses associated with organic mental disorders (Nasrallah and Tandon, 2009). Most veterinarians are familiar with acepromazine, one of the drugs in this class that is approved for veterinary medicine (e.g., Atravet, PromAce, or ACE; sometimes incorrectly called acetylpromazine). Acepromazine and other sedatives in this class are discussed in more detail in Chapter 14. Since the conventional antipsychotics produce neurological side effects, they are sometimes called *neuroleptics*. This term is generally not applied to newer, atypical antipsychotics for which neurological side effects are less likely. Antipsychotics block central dopamine (DA) receptors, particularly of the subtype DA_2. Antipsychotics produce ataraxia, a state of relative indifference to external stimuli (Baldessarini, 1995). Most antipsychotics are metabolized by the CYP 450 enzymes belonging to family 2 and 3; therefore it is possible that drug–drug interactions described for people also would be a concern for animals (Simpson and Papich, 2003).

Except for acepromazine (and Prolixin for horses), antipsychotics are not commonly used in modern veterinary behavioral medicine for a number of reasons. First, small animals are rarely diagnosed with "psychosis", and the anxiolytic properties of antipsychotics in animals are minimal. Second, side effects limit their usefulness. When animals are given traditional antipsychotics at relatively high or repeated doses, they often develop catalepsy, a syndrome with immobility, increased muscle tone, and abnormal postures, although reflexes (including the bite reflex) are preserved. Most veterinarians are familiar with the effects of acepromazine on dogs and cats. Third, spontaneous motor activity, caused by dopamine-receptor blockade in the striatum and inactivation of dopamine neurons in the substantia nigra may result from the administration of phenothiazines to animals (Nasrallah and Tandon, 2009). Finally, other important side effects of antipsychotic drugs, summarized below, can be unacceptable.

Antipsychotics can cause extrapyramidal signs (EPS) because of their effect of inhibiting the action of dopamine. EPS are most likely in older, high-potency antipsychotics such as haloperidol. EPS documented in humans include pseudoparkinsonism (stiffness, tremor, shuffling gait), akathisia (motor restlessness), and acute dystonic reactions (tightening of facial and neck muscles). The involuntary muscle movements of EPS have been confused with seizures. Antipsychotic drugs may also reduce blood pressure and elevate prolactin levels. One subclass of antipsychotics, the phenothiazines, may disinhibit learned responses (Aronson, 1999) and may inhibit the learning processes necessary for behavior modification techniques. It has been reported in several textbooks that this group of drugs, particularly acepromazine, increases the risk of seizures in animals and may actually be contraindicated in animals at risk of seizures. However, clinical studies have shown that acepromazine *does not* increase the risk of seizures in dogs (Tobias et al., 2006; Garner et al., 2004; McConnell et al., 2007).

These EPS should not be confused with another adverse effect of long-term antipsychotic medication called *tardive dyskinesia*. Tardive dyskinesia is characterized by oral–facial, limb, or truncal dyskinesia or twisting postures. The differentiation is that EPS usually occur soon after administration of the drugs, while tardive dyskinesia occurs after prolonged chronic treatment. The other important differentiation is that EPS are believed to be caused by a deficiency of dopamine and tardive dyskinesia is caused by an excess of dopamine, or increased dopamine receptor sensitivity caused by chronic administration. Decreasing the dose or withdrawal of the antipsychotic drug will worsen tardive dyskinesia. To our knowledge, tardive dyskinesia has not been described clinically in veterinary patients, though rodent models have been described.

Historically, one phenothiazine antipsychotic, acepromazine (PromAce, ACE, Atravet), has been used in the management of veterinary behavior problems, such as noise phobia, by reducing animals' general attendance to environmental stimuli and producing sedation. The effectiveness of acepromazine as an oral anxiolytic is often disappointing and causes undesirable side effects (Overall, 1998a). However, its intramuscular use may decrease presurgical patient apprehension and reduce the dose of other drugs used as general anesthetics (Light et al., 1993). It also may reduce the dose of other coadministered anesthetics. Owing to the sedative and extrapyramidal effects, acepromazine is not satisfactory for chronic administration. Other agents, such as the benzodiazepines or antidepressants, are preferred because they are more specific for their antianxiety effects and have fewer side effects. A small proportion of companion animals – especially cats – that are administered acepromazine orally will experience spontaneous motor activity, possibly akathisia.

A unique adverse effect reported in horses is penile prolapse. It is usually of short duration, but can last as long as 4 hours and can lead to paraphimosis. Because acepromazine is not used to modify behavior in horses, and is used primarily as an anesthetic adjunct, more detailed information about this adverse effect is listed in Chapter 14.

Phenothiazines have been used to treat compulsive behaviors not satisfactorily responsive to serotonergic drugs or in combination with serotonergic agents (Goodman et al., 1990). Dopamine has been implicated in some forms of stereotypic behaviors, perhaps because of the effect of serotonin (Kennes et al., 1988). Dopaminergic agents such as apomorphine and amphetamine and the dopamine precursor L-dopa can induce stereotypies in animals (Goodman et al., 1990). Thioridazine has been used in one case of aberrant motor behavior in a dog (Jones, 1987). In 2000, proprietary thioridazine (Mellaril) added a label warning that the drug has been shown to prolong the QTc interval and been associated with arrhythmias and sudden death in humans. It was recommended that thioridazine not be used concurrently with fluvoxamine, fluoxetine, paroxetine, propranolol, pindolol, or any drug that affects the QTc interval of the EKG or the CYP2D6 enzymes.

At this time, there is not sufficient information available to recommend safe dosage regimens for the majority of drugs in this class. The side effects associated with the traditional antipsychotics may not apply to the newer drugs, although immobility and transient loss of conditioned responses may be observed. At present their high cost and lack of published data make them impractical for animal use.

Anxiolytics

The anxiolytic drugs include benzodiazepines, azapirones, barbiturates, and antihistamines. Antidepressants (discussed separately, in Section Antidepressants) also have anxiolytic properties. Discussed here are the benzodiazepine and azapirone classes, as well as a special class, nonbenzodiazepine hypnotics.

Benzodiazepines

The benzodiazepines (BZDs) constitute a large class of drugs with a long history of safe and efficacious use in humans. Examples used in veterinary medicine are shown in Figure 18.1. All drugs in the class act on BZD receptors in the CNS to facilitate $GABA_A$, an inhibitory neurotransmitter. They are not direct inhibitors of the GABA receptor site, but modulate the GABA receptor to produce the desired effects. After binding to the $GABA_A$ receptor, these drugs enhance the GABA-mediated conductance through ionic channels and stabilize excitable membranes. The effects of BZD on behavior may be attributed to potentiation of GABA pathways that act to regulate release of monoamine neurotransmitters in the CNS. Examples of drugs in this class with veterinary application are diazepam, clorazepate, alprazolam, lorazepam, oxazepam, orazepam, and temazepam. Anesthetic uses of benzodiazepines are discussed in more detail with anesthetic agents in Chapter 14. The use

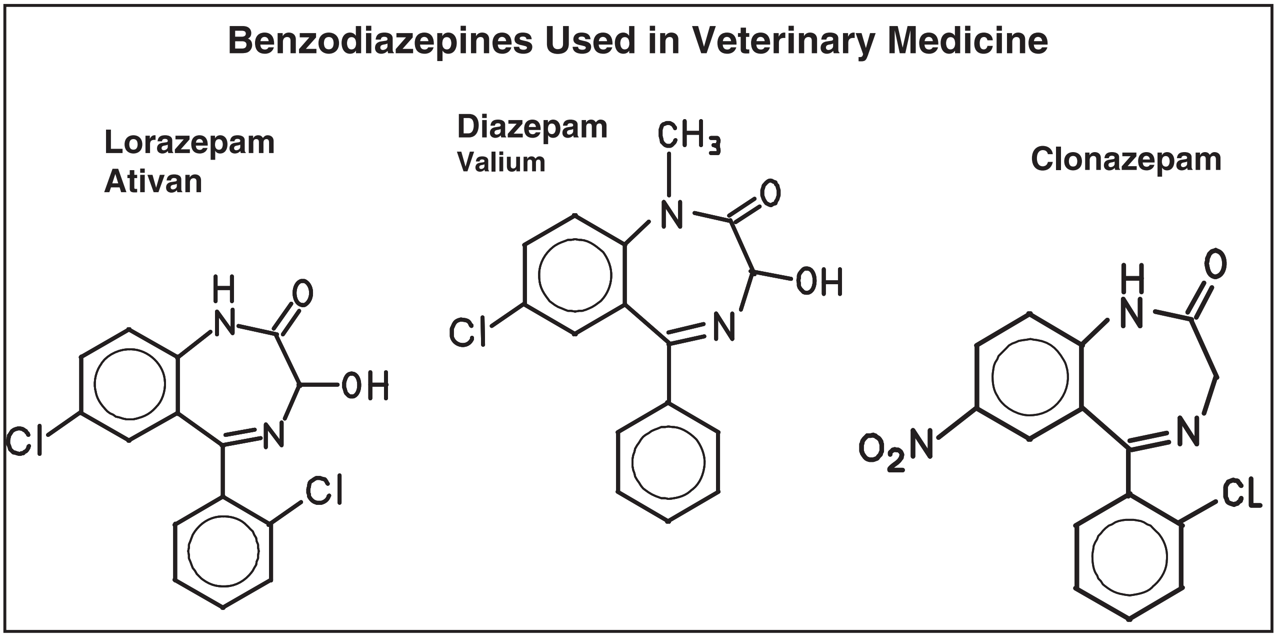

Figure 18.1 Benzodiazepines used in veterinary medicine. Lorazepam (left), diazepam (center), and clonazepam (right).

of benzodiazepines for treating seizures is discussed in Chapter 17 on anticonvulsant drugs.

There are more differences in the pharmacokinetic properties among these drugs than differences that affect the receptor (pharmacodynamic effect). BZDs are used in humans primarily for generalized anxiety disorder or panic disorder (Sheehan and Raj, 2009); they are used similarly in small animals (Simpson and Simpson, 1996b). Dosing schedule can affect pharmacokinetics. For example, diazepam given one time for anxiety will have a lower maximal nordiazepam concentration compared to the same BZD given twice daily (Sheehan and Raj, 2009; Forrester et al., 1990).

After oral administration, behavioral responses to BZDs generally occur within 1 hour, although conflicting studies in animals suggest that the anxiolytic effects are greater after they have been administered for several days (File, 1985). Sedation, ataxia, muscle relaxation, increased appetite, paradoxical excitation, and memory deficits may be observed (Roy-Byrne and Cowley, 1991). Tolerance to sedation, ataxia, and muscle relaxation may develop over the first few days of therapy (Löscher and Frey, 1981). Animals may become ataxic and unstable; therefore, pet owners should be cautioned to assist older animals to avoid falls. Animals should be observed for hyperphagia when given BZDs on a regular basis. Agitation and restlessness may occur as an idiosyncratic response to BZDs. Paradoxic reactions of excitement have been observed in dogs, particularly with administration of alprazolam. If these are observed, the drug should be discontinued and another drug from another class should be selected. Amnesia from BZD has been observed in humans for many years (King, 1992). Also, in animals, memory deficits and diminished conditioned responses may be observed, that is the animal may seem to “forget” what it has been previously taught. Difficulty in learning new behaviors, such as desensitization protocols, may be affected by the memory deficits.

At routine doses, BZDs have little, if any, effect on cardiovascular and respiratory systems (Sheehan and Raj, 2009). BZDs may disinhibit behavior. In humans, manifestations of disinhibition include hostility, aggressiveness, rage reactions, paroxysmal excitement, irritability, and behavioral dyscontrol (Dietch and Jennings, 1988). These effects are also reported in animals (Dodman, 2000), thus benzodiazepines should be used with caution in aggressive animals, particularly dogs, since bite inhibition may be lessened. The potential for behavioral disinhibition serves as a contraindication for the use of benzodiazepines in fearful but aggressive dogs. Bite inhibition may be diminished and the net effect may be an increased, rather than decreased, tendency to bite. Benzodiazepines are controlled substances with the potential for human substance abuse. Pet owners should be screened prior to prescribing and refill requests should be carefully scrutinized.

Although BZDs have a high safety margin, occasionally animals may be exposed to overdoses (accidental ingestion, for example) or have a paradoxical, unexpected reaction. In these instances it may be necessary to reverse the effects. Flumazenil (Romazicon) is a benzodiazepine-receptor antagonist and will inhibit the effects of BZDs. Flumazenil has been used to counteract the adverse effects of large overdoses of BZDs.

After daily administration for more than 1 week, a benzodiazepine should be withdrawn gradually to avoid discontinuation syndrome. Discontinuation syndrome, especially common in high-potency benzodiazepines such as alprazolam, includes nervousness, tremors, or even seizures (Roy-Byrne and Cowley, 1991; Roy-Byrne et al., 1993). The longer a BZD is administered and the higher the dose used, the greater the likelihood of withdrawal reactions when it is discontinued, especially abruptly (Janicak et al., 2011). Signs may be reversed by administration of the BZD. Discontinuation syndrome may be avoided by tapering the BZD dose 25% per week for 1 month. If a discontinuation reaction is observed, signs can be relieved by administering the implicated drug.

BZDs are used in dogs to treat fears and phobias as well as generalized anxiety. Benzodiazepines may be combined with a tricyclic antidepressant such as clomipramine to decrease latency to effect and reduce the panic-like states of thunderstorm phobia (Crowell-Davis et al., 2003) and separation anxiety (Herron et al., 2008). Among cats, BZDs are used for management of urine spraying, travel, and generalized anxiety, such as anxiety associated with changes in a new home environment.

Diazepam

Diazepam (Valium) is the best known of the BZD (Figure 18.1). It has been used for behavior disorders as a sedative, muscle relaxant, anxiolytic, anticonvulsant, and adjunct for anesthesia. Its high lipophilicity and rapid distribution make it suitable for the emergency treatment of seizures because it crosses the blood–brain barrier quickly. Its high lipophilicity also allows it to be absorbed across membranes quickly and is even rapidly and almost completely absorbed from a rectal or nasal administration (Papich and Alcorn, 1995; Musulin et al., 2011). However, the vehicle carrier is not suitable for intramuscular administration.

The pharmacokinetics of diazepam are complex, but have been examined in both dogs and cats (Sheehan and Raj, 2009; Löscher and Frey, 1981; Papich and Alcorn, 1995; Cotler et al., 1984; Musulin et al., 2011). Diazepam undergoes metabolism first to a demethylated metabolite, desmethyldiazepam (also called nordiazepam), and then to oxazepam. Both of these metabolites are active, but not as active or as lipid soluble as diazepam. Desmethyldiazepam is believed to have anticonvulsant properties that are equal to (Randall et al., 1965) or about one-third of (Frey and Löscher, 1982) the potency of diazepam. The pharmacokinetics of diazepam illustrate the tremendous species differences in clearance and elimination. In people, diazepam is considered a drug with low hepatic clearance and a long half-life. The half-life in people is 43 hours, (but may range from 24 to 48 hours) and systemic clearance is 0.38 ml/min/kg. In dogs, the half-life was less than 1 hour, and clearance is in excess of liver blood flow at 57–60 ml/min/kg in one study (Papich and Alcorn, 1995), but had a longer half-life of 5.6 hours and slower clearance (11.5 ml/kg/min) in another study (Musulin et al., 2011). Cats have slower clearance than dogs with the half-life in cats of 5.5 hours and the systemic clearance is 4.7 ml/min/kg (Cotler et al., 1984). In all species, the metabolites of diazepam have longer elimination half-lives than diazepam. For example, the half-life of desmethyldiazepam is 51–120 hours in people, 21.3 hours in cats, and 2.2–2.8 or 6.7 hours for dogs (Papich and Alcorn, 1995; Cotler et al., 1984; Musulin et al., 2011). These differences show that for long-term treatment, diazepam is not suitable for dogs because frequent administration is necessary to avoid high peaks and low troughs. However, its short half-life and ability to attain therapeutic concentrations makes it suitable for short-term use. This large difference in pharmacokinetics among species for diazepam means that information published for diazepam in humans will not apply to dogs. For example, CYP 450 enzyme inhibition and other drug interactions cited for people are not likely in dogs because of the already-high systemic clearance. But, because liver clearance is dependent primarily on hepatic blood flow, changes in hepatic perfusion will drastically affect diazepam clearance. Clearance is expected to be altered in dogs with congenital or acquired hepatic vascular shunts.

As an oral anxiolytic in solid form in dogs, it has a benign taste, and is relatively easy to administer directly or by mixing in moist food. However, particularly for panic-like states of thunderstorm phobia and separation anxiety, clinicians anecdotally report the anxiolytic performance of diazepam to be disappointing. Because hepatic clearance is high in dogs, oral doses are likely to be less effective than IV doses. If used orally in dogs, high doses may be sufficient to produce ataxia but insufficient to reduce anxiety. Other agents, such as alprazolam, may be more satisfactory, or a regime of daily, rather than PRN dosing, may be more effective. Alternatively, rectal or nasal administration of diazepam can be considered (Papich and Alcorn, 1995; Musulin et al., 2011).

In cats, oral diazepam has been used for treatment of urine spraying (Cooper and Hart, 1992; Hart et al., 1993). In open trials, efficacy was approximately 55%, although relapse was common on discontinuation (Marder, 1991; Cooper and Hart, 1992). Concerns about side effects from oral use in cats have decreased its application in veterinary medicine. The most serious adverse reaction associated with diazepam in companion animals is that of idiosyncratic hepatic necrosis in cats. Hepatic necrosis from diazepam is a rare but often-fatal condition, and has been documented in cats given oral diazepam. The specific pathogenic mechanism is not known (Center et al., 1996; Hughes et al., 1996). Diazepam undergoes complex metabolism to intermediate compounds. It is possible that in susceptible cats, an aberrant metabolite is produced that is responsible for the hepatic toxicosis. In the cats reported, the reaction occurred within 7 days of oral administration of generic or proprietary diazepam (Center et al., 1996; Hughes et al., 1996). It is possible that the metabolites responsible for the toxicosis are more likely to be produced from oral administration because of first-pass metabolism, compared to parenteral administration (van Beusekom, 2015). Idiosyncratic hepatic necrosis has not been reported after administration of other oral benzodiazepines, although that negative finding does not eliminate the possibility. However, the adverse event may be less likely with lorazepam and oxazepam, which are conjugated directly without undergoing intermediate metabolism. Alprazolam and temazepam appear to have only one intermediate (alphahydroxy) metabolite before undergoing conjugation. Compared to diazepam, these alternative drugs may be less likely to induce hepatic toxicosis in cats but safety studies are needed to confirm this theory.

Clorazepate

The BZD clorazepate (Tranxene) is metabolized in the acidity of the stomach to its active metabolite, nordiazepam, before absorption (Sheehan and Raj, 2009; Forrester et al., 1993). Clorazepate is used in dogs for treatment of anxiety disorders, particularly thunderstorm/noise phobia. Mean peak nordiazepam levels were detected approximately 98 minutes after a single oral dose of clorazepate, and 153 minutes after multiple oral doses (Forrester et al., 1990). The elimination half-life after a single dose (284 minutes) was not significantly different than after multiple doses (355 minutes) (Forrester et al., 1990). An oral dose of 2 mg/kg q 12 h maintains concentrations of the active metabolite, nordiazepam, in the range considered therapeutic in humans (Forrester et al., 1990). Excessive ataxia and sedation are uncommon (Forrester et al., 1990). Although available in a sustained-delivery formulation, one pharmacokinetic study in dogs found no difference in the serum disposition compared to immediate-release clorazepate (Brown and Forrester, 1991).

Alprazolam

Alprazolam (Xanax) is a high-potency benzodiazepine shown in humans to be an effective treatment for panic disorder (Figure 18.1). Its use has increased since the availability of generic forms. It is used in dogs to treat the panic-like states of separation anxiety, thunderstorm phobia, and other phobias, as well as generalized anxiety. In people, it has a more rapid onset of action and shorter elimination half-life than diazepam, but these comparisons have not been reported for animals. In humans (Sheehan and Raj, 2009; Brandwein, 1993), plasma concentrations vary greatly among patients administered identical doses of alprazolam. As in humans, higher doses of alprazolam may be required for panic-like states in dogs, such as thunderstorm phobia and separation anxiety, compared to general anxiety. Thus, individualized dosing may be required to achieve treatment success with the fewest adverse effects (Sheehan and Raj, 2009). Paradoxical excitement occurs in some canine patients given alprazolam. In such cases, the drug should be discontinued and a drug in another class should be selected. The mechanism of this paradoxical reaction is not known. Canine patients receiving alprazolam at a moderately high dose once a day, as may occur with separation anxiety or thunderstorm phobia, are at risk for withdrawal-induced anxiety or tremors prior to the next day's dose, due to its short elimination half-life (Crowell-Davis and Murray, 2006). This may be avoided by administering the drug twice a day and not skipping doses. To terminate the drug, alprazolam should be withdrawn slowly, decreasing the dose over weeks.

Oxazepam and Lorazepam

As mentioned previously, oxazepam (Serax) and lorazepam (Ativan) are metabolized directly via phase II conjugation to inactive compounds (Sheehan and Raj, 2009). Both oxazepam and lorazepam have been used by veterinarians as sedatives, anxiolytics, and anticonvulsants, but they are not as well-known as diazepam. In cats, oxazepam has been used as an appetite stimulant. There are no active metabolites for either oxazepam or lorazepam. Because conjugation reactions are usually preserved, even when there is hepatic disease, these drugs are recommended for individuals with compromised liver function, for aged canine subjects in which metabolism may be slowed (Sheehan and Raj, 2009), and in cats, in which phase II metabolism may be less likely to trigger idiopathic hepatic necrosis. Lorazepam has the advantage of a greater and more prolonged distribution to the CNS than other BZDs. Lorazepam in healthy dogs has a half-life of 0.88 hours, a systemic clearance less than half that of diazepam at 19.3 ml/min/kg, and oral availability of 60% (Papich, unpublished research). Therefore, as an oral drug it may be a suitable alternative to diazepam.

In dogs, benzodiazepines may be used with tricyclic antidepressants for treatment of thunderstorm phobia (Crowell-Davis et al., 2003) and separation anxiety (Takeuchi et al., 2000). When alprazolam is given concomitantly with fluoxetine in humans, the result is a 30% increase in alprazolam levels (but no significant increases in fluoxetine or norfluoxetine plasma concentrations) due to CYP3A inhibition (Lasher et al., 1991). Therefore, coadministration may permit a lower dose of alprazolam to be effective. Fluvoxamine inhibits the CYP3A4 enzyme and can be associated with increased levels of alprazolam (Sheehan and Raj, 2009). In fact, the use of a BZD and an SSRI is a useful strategy with panic disorder in humans refractory to single drug therapy (Stahl, 2013). Similar strategies may be helpful in animals, particularly dogs. Oxazepam has been shown in humans to decrease turnover of serotonin and norepinephrine (Sheehan and Raj, 2009). In contrast, in one pharmacokinetic study in dogs, clorazepate was used concurrently with phenobarbital (Forrester et al., 1993). The amount of the active metabolite nordiazepam in circulation during each dose interval was significantly reduced compared to administration of clorazepate alone (Forrester et al., 1990).

Azapirones

This class of anxiolytics is represented clinically by one drug, buspirone (Buspar). Buspirone was the first nonsedating, nonbenzodiazepine anxiolytic drug to be developed and marketed (Robinson et al., 2009). Buspirone acts as a full agonist at presynaptic $5HT_{1A}$ receptors, with resulting decrease in serotonin synthesis and inhibition of neuronal firing. It also acts as a partial agonist at postsynaptic $5HT_{1A}$ receptors. In serotonin deficit states, buspirone acts as an agonist (Robinson et al., 2009). Buspirone also has dopaminergic effects.

Buspirone is not a substrate for CYP 450 enzymes, nor does it inhibit them (Robinson et al., 2009). It has no interactions with benzodiazepines and there are no withdrawal concerns after long-term use (Stahl, 2013). In humans, buspirone has been effective for treatment of generalized anxiety disorder, but not for the control of panic disorder. Buspirone has demonstrated efficacy in certain animal models of anxiety, such as the conditioned avoidance response. In dogs, buspirone does not appear to be particularly therapeutic for the panic-like condition of thunderstorm phobia or separation anxiety, but it has been used for generalized anxiety.

Because it has a short elimination half-life, buspirone must be administered two or three times per day. Buspirone has a benign taste and may be given with food. In contrast to benzodiazepines, buspirone produces no sedation, no memory or psychomotor impairment, and no disinhibition phenomenon. Unlike the benzodiazepines, buspirone produces no immediate behavioral effects. Its beneficial effects are not observed until administration for several weeks. Side effects are uncommon and mild, but may be noted immediately. They include gastrointestinal signs and alterations in social behavior (often reported as increased "friendliness"). Buspirone has no potential for human abuse.

In cats, buspirone is used to modulate states of high arousal, including feline urine spraying. In an open trial, improvement was observed in 55% of cats, with a 50% relapse rate following the cessation of treatment (Hart et al., 1993). It has also been used to reduce anxiety in the "pariah" cat in cases of intercat aggression within a household (Overall, 1994a, 1999a).

Buspirone can be used to augment certain antidepressants. If used with an SSRI, increased efficacy is possible if intraneuronal serotonin has been depleted. Buspirone also may act directly on autoreceptors to inhibit neuronal impulse flow, possibly allowing repletion of 5HT stores. Also, buspirone may act at $5HT_{1A}$ receptors to aid in the targeted desensitization of $5HT_{1A}$ autoreceptors (Stahl, 2013). In humans, buspirone may be used to augment SSRI treatment for obsessive–compulsive disorder (OCD) with success in some studies (Janicak et al., 2011) but not others (Grady et al., 1993). In dogs, buspirone has been used with tricyclic antidepressants to treat separation anxiety (Takeuchi et al., 2000) and with an SSRI (fluoxetine) to treat a complex case involving anxiety, aggression, and stereotypic behavior (Overall, 1995).

Nonbenzodiazepine Hypnotics

In cases of acute-onset and severe phobic states, such as thunderstorm phobia and separation anxiety, there is a need for safe and rapid reduction in responsiveness to environmental stimuli and initiation of sleep, with relatively short duration of action and rapid recovery. The unpredictable and often disappointing effect of benzodiazepines and phenothiazines, and the long latency to effect of buspirone, leave a void with regard to such application. Nonbenzodiazepine hypnotics hold some promise, since they are used to facilitate and maintain sleep for 3–7 hours in humans, although no published reports on their clinical use in dogs are available to date. Drugs in this class include zaleplon (Sonata), eszopiclone (Lunesta), and zolpidem (Ambien). These drugs are sometimes referred to as the *Z-drugs* to distinguish their effects from traditional benzodiazepines. Like benzodiazepines, zolpidem potentiates the action of GABA, an inhibitory neurotransmitter. However, it does not cause muscle relaxation or produce anticonvulsant properties. $GABA_A$, a target site of benzodiazepines, has omega-1, -2, and -3 receptors. Benzodiazepines act on all receptors, but zolpidem, and other drugs known as Z-drugs, only act on the omega-1 receptor to produce sedation. Zaleplon has an ultrashort elimination half-life in humans, suggesting it unlikely to be useful in dogs. The newest agent, eszopiclone, is registered for the long-term treatment of insomnia in humans (Brielmaier, 2006), but there are no reports of its clinical use in animals.

Zolpidem is a sedative of the imidazopyridine class. The usual human dose is 5–10 mg (also available as *CR*, controlled release formulation), used to promote and maintain sleep. In a report of 33 cases of accidental ingestion of zolpidem by dogs presented to a poison control center, 40% exhibited signs of depression/sedation and 40% demonstrated signs of hyperactivity (Richardson et al., 2002). Although doses were extreme (up to 21 mg/kg), all dogs recovered. Controlled, single-dose administration of a high (0.5 mg/kg) and low (0.15 mg/kg) dose of zolpidem in dogs showed either no clinical effect (low dose) or paradoxical CNS stimulation followed by mild sedation (high dose) (Giorgi, 2012). Other signs reported in research dogs included vocalization, restlessness, anxiety, dysphoria, rage reaction, excitement, muscle spasticity, and hyperreflexia. These findings suggest that zolpidem is unlikely to be clinically useful in dogs.

Antidepressants

This group comprises perhaps the largest group of agents used to manage behavior problems in small animals. This category of antidepressants includes a number of classes of drugs. Depending on the reference consulted, various classification systems have been used to group these drugs. Following convention, here, the structurally similar tricyclic antidepressants (TCAs) are discussed together. Drugs in this class include amitriptyline, imipramine, doxepin, and clomipramine. The functionally similar selective serotonin reuptake inhibitors (SSRIs) are discussed as a class. Drugs that act to inhibit the enzyme monoamine oxidase (MAOIs) are discussed as a class. Grouped as a separate "atypical" class are those antidepressants that fall outside the aforementioned three groups. This group includes the newer, heterocyclic drugs, such amoxapine, maprotiline, venlafaxine, and mirtazapine, which resemble TCAs, and older drugs, such as trazodone and bupropion, which have distinct chemical structures. The classes described above differ in their mode of action, their side effect profile, and their relative efficacy in certain behavioral disorders.

All antidepressants have important antianxiety properties, and at routine doses are generally well tolerated by animals. To some extent, all share a similar action, which is to alter neurotransmitter concentration (primarily norepinephrine and serotonin) at the receptor sites. The unifying theory that explains their efficacy is the *monoamine theory of depression* described by Schildkraut in 1965 (Maes and Meltazer, 1995), which stated that depression in people is caused by a deficiency of monoamine neurotransmitters. Initially, this theory focused on norepinephrine, but it became clear later that serotonin (5HT) also was an important neurotransmitter. The relationship of the mechanism to the neuronal effects and clinical response is complex. The action affecting reuptake of neurotransmitters occurs rapidly, but the clinical response may take days to weeks for maximum effect. This implies that the increased presence of neurotransmitters norepinephrine and 5HT also may affect the sensitivity of receptors, either presynaptically or postsynaptically.

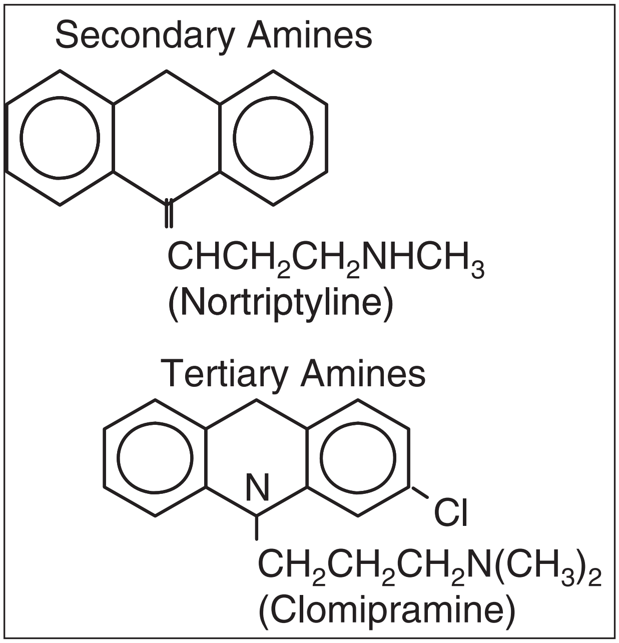

Figure 18.2 Tricyclic antidepressants (TCAs) used to treat behavior disorders in veterinary medicine. Nortriptyline is a secondary amine and clomipramine is a tertiary amine. Most of the other TCAs used in veterinary medicine – amitriptyline (Elavil), doxepin (Sinequan), and imipramine (Tofranil) – are also tertiary amines.

Tricyclic Antidepressants

The tricyclic antidepressants (TCAs) are so called because they have a three-ring nucleus (Figure 18.2). Chemically they resemble phenothiazines, but their actions differ considerably. The TCAs inhibit the reuptake of 5HT and norepinephrine. Specific drugs vary in the extent to which they inhibit one transmitter more than the other. Some of these drugs familiar to veterinarians are human-label drugs that are used off-label. These include the tertiary amines amitriptyline (Elavil), doxepin (Sinequan), and imipramine (Tofranil). The secondary amines, such as nortriptyline (Pamelor) and desipramine (Norpramin), are not as well known to veterinarians. Secondary amines (Figure 18.2) are relatively selective inhibitors of norepinephrine, but the tertiary amines inhibit both serotonin and norepinephrine (Figure 18.3). Clomipramine (Clomicalm, veterinary label; and Anafranil human label), another tertiary amine, is most selective among the TCAs for blocking the reuptake of 5HT. TCAs also have antagonist activity for the α-adrenergic (α_1) receptor, and can produce antihistaminic and anticholinergic effects. The antagonist activity on these receptors is responsible for some of the side effects reported with TCAs, but most likely plays little role in their efficacy. As with other drugs in this chapter, there are species-specific differences in metabolism, elimination, and susceptibility to side effects that will be discussed in more detail with specific drugs.

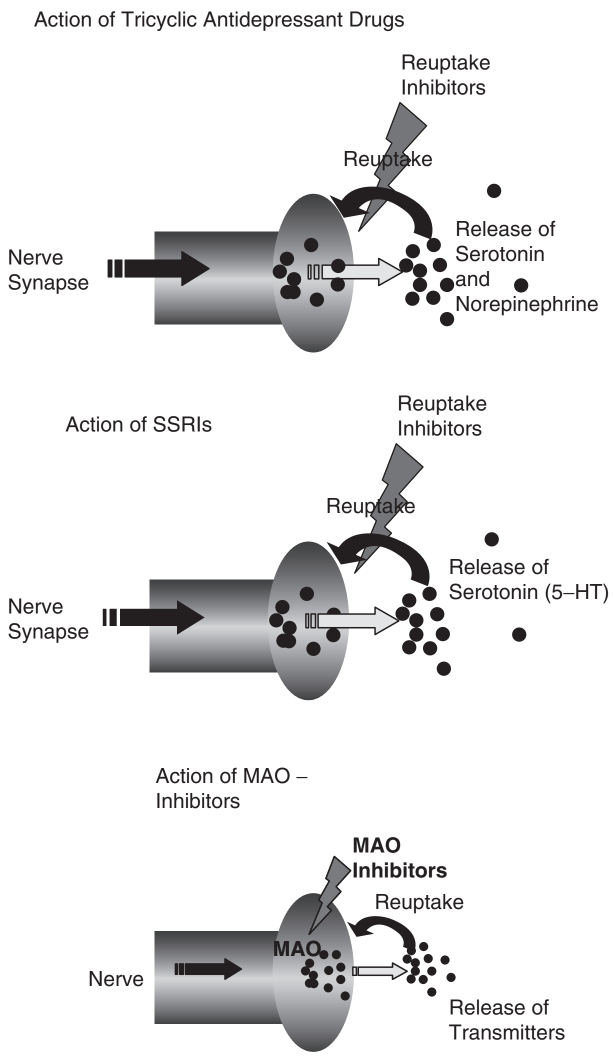

Figure 18.3 Action of drugs used to treat behavior disorders in animals. Tricyclic antidepressants (top panel) inhibit the reuptake of serotonin and norepinephrine. Selective serotonin reuptake inhibitors (SSRI) (middle panel) selectively inhibit reuptake of serotonin without much effect on other receptors. Monoamine oxidase inhibitors (MAO-inhibitors) (bottom panel) inhibit the enzymatic breakdown of monoamines in the presynaptic nerve terminal. Specific types of MAO exist in the nervous system, such as MAO type A and MAO type B, depending on location.

TCAs have a long history of efficacious use in humans, but in recent years, they have been largely replaced by the more specific selective serotonin reuptake inhibitors (SSRI). The low cost, efficacy, and tolerance of the TCAs make them particularly useful in veterinary behavioral therapy. In general, the TCAs modulate excessive arousal and reduce anxiety. TCAs may enhance learning in specific circumstances (Mills and Ledger, 2001). Unlike the benzodiazepines, the TCAs do not disinhibit behavior. TCAs are used in dogs to manage mild aggression, canine compulsive disorders, and various anxiety states (Juarbe-Diaz, 1997a,b). TCAs may be used in cats to control certain forms of aggression, inappropriate urination and spraying, excessive grooming, anxiety states, and excessive vocalization. In horses the TCAs have had limited use and there is little known about pharmacokinetics. Tricyclic antidepressants, such as amitriptyline or imipramine, via their serotonin and norepinephrine reuptake inhibitor effects, may enhance behavioral calming; side effects can include mild sedation and anticholinergic effects in horses. Imipramine has been used to reduce anxiety in breeding stallions and is associated with masturbation and erection in stallions when in a sexual context. At high doses, imipramine (2–4 mg/kg q 24 h, PO) can cause muscle fasciculations, tachycardia, and hyperresponsiveness to sound, likely due to norepinephrine effects.
